(3) The large number of rows of teeth in fresh-water mollusca are provided, not because of their tendency to decay or to be worn out in the exercise of their natural functions in eating, but because of their constant exposure to injuries, the loss being replaced by the posterior rows. For the same reason, those mollusca which use their teeth to bore holes through the shells of others are provided with remarkably long radulæ, while land and lagoon species, which are constantly exposed to the attacks of their natural enemies, are also provided with longer radulæ than those commonly possessed by the inhabitants of semi-stagnant rivers and still pools.

Annotations.

Pathogenesis of Epilepsy (Aldo Massaglia, M.D., *The Journal-Lancet*, July 15, 1924).—The experiments reported determined in the animals a morbid condition which may be compared with, if not considered equal to, some forms of epilepsy. The results lead to the supposition that some forms of the disease (epilepsy) may be caused by a hypofunction of the parathyroid glands, which create the predisposition to the convulsive attack, accompanied by a hypersecretion of the islands of Langerhans which lowers the blood-sugar content. It is suggested, then, in cases of idiopathic epilepsy, to try using a treatment based upon the administration of parathyroidin and sugar—a treatment which will probably induce a cure.

Amœbic Abscess of the Liver. Report of a Case Complicated by Subphrenic Abscess (*Journal of the American Medical Association, June* 27, 1925).—It is considered that it might be possible to treat a liver abscess successfully, but the destruction of the liver is so extreme that the patient dies as a result of lack of liver tissue. In the last ten years, at the University Clinic at Philadelphia, there has been one case of amœbic abscess of the liver and seven cases of subdiaphragmatic abscess. In the same length of time there occurred eight ordinary abscesses of the liver. The clinic has been much interested in the work done by the roentgenologic department. One cannot depend on the position of the diaphragm in the differentiation of a liver abscess from a subdiaphragmatic abscess. Exploratory puncture, starting high in the chest wall, to rule out empyema, which complicated subdiaphragmatic or liver abscess in three cases, is ardently advocated. Following operation, a small bronchoscope through the transpleural opening has been used. Another point of interest is that it is believed that subdiaphragmatic abscesses start as liver abscesses.

The Nutrition of Mycorrhiza Plants: Calluna Vulgaris (M. C. Rayner, D.Sc., *British Journal of Experimental Biology*, January, 1925).—An interesting account is given of the formation and seasonal development of mycorrhiza in Ling (*Calluna vulgaris*). A record was obtained for the first time of the digestion of the intracellular complex of mycelium in the mycorrhiza cells and the cytology of the process is described. Fresh information of the distribution of the endophyte in the shoot tissues was obtained, and confirmed by experimental work on cuttings struck in sterilized sand under controlled conditions. The endophyte was recovered and identified from the shoot. These results are compared with those described by Christoph, whose observations were interpreted in the light of the account now given of the information of "suppressed mycorrhiza" in roots of cuttings and also in those of seedlings and mature plants when certain conditions exist in the rooting medium. It is pointed out that the "obligate relation" in *Calluna* is associated with *infection and seedling development* and not with *mycorrhiza formation and growth*. The view is expressed that plants would probably grow quite well without mycorrhiza could seedlings be raised free from infection. The formation of mycorrhiza in all roots is the rule of nature; the activities of endophyte and its digestion products are presumably related to the nutrition of the plant and may be correlated with its growth in particular soils. Evidence for exchange of nutritive material is given. The view has been reached that such exchange exists, with a "balance of profit" on the side of the vascular plant. It is suggested, in view of its application to cases for which experimental data are not available, that the term "symbiosis," as applied to mycorrhiza plants, should be used in the older sense defined by de Bary.

The Feeding Habit of Termite Castes and its Relation to their Intestinal Flagellates (L. R. Cleveland, *Biochemical Bulletin*, No. 5, May, 1925).—The conclusions of this paper are: At every stage in the life-cycle of any caste where wood is eaten, protozoa are present. When wood is not eaten or obtained in some way, protozoa are never present. Second and third form young adults have lost the ability to eat wood. The protozoa in these castes disappear concomitantly with the loss of the ability of their host to feed on wood, and by the time the wood-eating ability is lost, they have all disappeared. This occurs about the time of the final moult and is perhaps brought about by the feeding of salivary secretions which take the place of the wood diet. In all castes, the protozoa are lost during moulting, but they are soon regained, except in the final moult of the second and third forms, in which forms they are never regained because, owing to the degeneration of their jaw muscles, these forms have lost the ability to eat wood. What causes jaw muscles to degenerate is not definitely known. It may be inherent in these castes, as much a part of them as anything else. If it is, then the salivary-feeding is hereby made necessary and takes the place of the wood diet when the jaw muscles degenerate. But a more plausible possibility is that these forms are fed on so much salivary secretion that they cease to feed on wood, and because of this their jaw muscles degenerate through

disuse, and thus the ability to feed on wood is lost forever. The first form and the worker always eat wood, except in the post-adult stage of the life-cycle of the first form where it, too, after having attained an old age, loses the ability to eat wood and becomes dependent on the workers and young undifferentiated nymphs (when present) which it has reared. It is noteworthy that mostly workers are raised in the first brood. Adult soldiers, owing to their large mandibles, cannot eat wood (cannot chew it) though they obtain it, together with protozoa from the ani of the xylophagous members of the colony. Soldiers, like workers, harbour protozoa throughout their life-cycle. Young soldiers (soldier nymphs) before they obtain the large mandibles, can chew wood for themselves. So can the second and third forms, during early life. A caste which cannot eat wood, or, thinking in terms of the protozoa, a caste which does not harbour protozoa, cannot live by itself. Such individuals are dependent on the wood-eating members of the colony for support; consequently adults of the second form, third form and soldier castes must be supported by other members of the colony. But the soldiers, in one sense, are not as difficult to support as the second and third forms, since they can digest for themselves the partially digested woody material which has passed through the alimentary canal of the xylophagous members of the colony before they receive it; while the second and third forms, since they feed exclusively on the salivary secretions, must subsist entirely on predigested food.

Contributions to Pathologic Anatomy of Syphilis. I. Syphilis of the Aorta (Edward L. Miloslavich, M.D., *Archives of Dermatology and Syphilology*, July, 1925).—Syphilis of the aorta is a morphologically characteristic disease which is localized in the elastic-muscular layer (mesaortitis) at the most proximal portion of the aorta, and which leads to an aortic insufficiency, occlusion of the coronary arteries and formation of aortic aneurysm. Syphilis of the aorta plays a dominant part in the pathology of syphilis. The syphilitic nature of this aortic disease is proved: by the presence of syphilitic histologic lesions (gummatous infiltrations); by the demonstration of *Spirochæta pallida* in the diseased aortic wall; by the positive reaction of the Wassermann test made on the blood taken during necropsies; by the frequent combination with other syphilitic organic diseases, such as syphilis of the central nervous system (general paralysis, tabes dorsalis, &c.), syphilis of the liver, testes, &c.; by its appearance at a relatively early age, and by its characteristic macroscopic and microscopic localization in the aorta itself, as compared to the localization of atherosclerosis of the same organ.

Toxicity of Oxygen for Protozoa in Vivo and in Vitro: Animals defaunted without Injury (L. R. Cleveland, *Biochemical Bulletin*, June 6, 1925).—The toxicity of oxygen at various pressures for four genera of termites has been determined. At a pressure of 3·5 atmospheres the protozoa are all killed in two genera in thirty minutes, one in thirty-five minutes and in another in forty minutes, while the termites themselves are not killed until forty-five hours. Thus, oxygen is more than forty times as toxic for the protozoa as it is for the termites. This makes it possible to remove all protozoa from termites very easily and without injury to the host. The protozoa of two termite genera were not killed at one atmosphere of oxygen even in ten days, while in two other genera they were killed in one and three days respectively. Cockroaches harbour many kinds of protozoa, all of which were removed by oxygenation at 3·5 atmospheres in three and a half hours. It is highly probable that all insect-inhabiting protozoa may be removed by oxygenation without injury to their hosts. If so, the rôle which insects play in the transmission of protozoa from man to man, from animal to animal, from animal to man and from plant to plant can be worked out much more effectively. Earthworms when oxygenated lose their ciliates and are uninjured by the process. Frogs harbour many protozoa. More than 150 experiments have been carried out on the oxygenation of frogs and all the intestinal protozoa may be removed without injury to the frogs. The protozoa of two water-breathing vertebrates, goldfish and salamanders, were all killed by oxygenation in less than one fifth of the time required to kill their hosts. It is highly probable that all intestinal flagellates and ciliates may be removed from all invertebrates and from all cold-blooded vertebrates by oxygenation and that none of these hosts will be injured. It is also possible that the sporozoa, amœbæ and blood-inhabiting protozoa may be removed from the same hosts in the same way and without injury to the hosts. Oxygenation experiments have been carried out on four genera of free-living ciliates and two of free-living flagellates. Oxygen is certainly just as toxic for some free-living ciliates as it is for parasitic ciliates; for others it is not. Oxygen in excessive amounts is toxic for all animals, but protozoa possibly take up a correspondingly larger amount of it as the tension or pressure is increased than do higher animals and for this reason are affected more adversely than termites, cockroaches, earthworms and frogs.

Urticaria Solaris. Report of a Case (L. G. Beinhauer, M.D., *Archives of Dermatology and Syphilology*, July, 1925).—The case reported is interesting because it deals with a skin reaction produced by exposure to the sunlight. The reaction was a typical urticarial wheal, which could be duplicated by exposure to the ultra-violet rays of the mercury-quartz lamp. Other efforts to produce this reaction failed, making it evident that some rays from the sun and some rays produced by the mercury-quartz lamp were similar, producing the same reaction. As in other cases reported along similar lines, the

patient belonged to an "allergic family." From the data obtained the author feels sure he is dealing with a specific sensitization of this patient's skin to the near ultra-violet rays.

The Effects of Oxygenation and Starvation on the Symbiosis between the Termite, Termopsis and its Intestinal Flagellates (L. R. Cleveland).—The results of these experiments, as regards the symbiotic relationship between termites and their intestinal protozoa, are in accord with those obtained by the incubation method (Cleveland 240). The symbiosis between these insects and their intestinal flagellates has now been clearly demonstrated by three entirely different methods, namely, incubation, starvation and oxygenation.

Lupus Erythematosus (Binford Throne, M.D., *Archives of Dermatology and Syphilology*, July, 1925).—In early cases of the discoid type, removal of focal infections before atrophy sets in, together with simple local treatment, seems curative. When atrophy is present, removal of focal infections has no curative value. Removal of focal infections before instituting radical treatment seems to prevent recurrences. Vaccine treatment was of no value. The blood complement-fixation test for tuberculosis seems to be of value in the diagnosis of the tuberculids. In lupus erythematosus a negative result is to be expected.

Dermatitis produced by the Portuguese Man-of-War (E. D. Crutchfield, M.D., July, 1925, *Archives of Dermatology and Syphilology*, July, 1925).—The tentacles of the Portuguese man-of-war contain an irritant substance capable of producing an acute dermatitis. The dermatitis varies from an urticarial line to a linear coagulation necrosis, varying with time of contact. The acute symptoms of the disease are alleviated by the application of weak antacid solutions. The lesions heal, leaving a hæmatogenous pigment, which is slowly absorbed. In some instances healing is followed by permanent scar formation.

Congenital Ichthyosiform Erythroderma (Richard S. Weiss, M.D., and Norman Tobias, M.D., *Archives of Dermatology and Syphilology*, August, 1925).—Six cases of congenital ichthyosiform erythroderma are reported equally divided between the sexes. The earliest time of appearance was at the age of two months, the latest at nine years. In four of the cases there was distinct familial tendency. The evidence in the literature, as well as in these cases, leads one to believe that there should be no differentiation between the wet and dry types, as the wet types seem to represent a superimposed bullous impetigo. Possibly some of these cases may indicate a transitional type of epidermolysis bullosa with elastic tissue changes. The pathology is similar to that of ichthyosis vulgaris. The cellular infiltrations in the corium are in all probability secondary to external irritation with resulting inflammation.

Dermatitis in Association with Disease or Injury of the Peripheral Nerves (S. William Becker, M.D., *Archives of Dermatology and Syphilology*, August, 1925).—A case is reported of eczematoid dermatitis of the right side of the face, appearing three weeks after section of the posterior root of the gasserian ganglion. Herpes at no time was suggested. Pyorrhœa and dental caries were also present on that side. The condition was little influenced by treatment, and had been present for about four years. Experimental and clinical observations would seem to indicate that toxic, infectious or mechanical irritation of the sensory nerves can be instrumental in producing this type of lesion.

Nodosites Juxta-Articulaires (Perpetuo D. Gutierrez, M.D., *Archives of Dermatology and Syphilology*, August, 1925).—All the cases treated yielded, though slowly, to neoarsphenamin. In some two injections sufficed to reduce a tumour of the size of a pigeon's egg to that of a pea. These patients, however, improved so much and the tumours were so reduced in size that they failed to return for further treatment. After the first injection, there was not much reduction in the size of the tumours; there was only softening of the hard cartilagenous consistency. On subsequent injection, however, the reduction in the size was marked.

Notes on Ornithobilharzia Odhneri n. sp. from the Asiatic Curlew (Ernest Carroll Faust, *Journal of Parasitology*, Reprinted, September, 1924).—A new species of avian schistosome, designated as *Ornithobilharzia odhneri*, is described from the curlew *Numenius arquatus*. The details of structure, particularly in the female worm, require certain amendments in the generic concept. The presence of Laurer's canal in *O. odhneri* with a direct opening to the dorsal surface, would make it seem likely that the organ may actually function for the reception of sperm directly from the male.

Studies on the Etiology of Heartwater. Rickettsia Ruminantium in the Tissues of Ticks Transmitting the Disease (E. V. Cowdry, *Journal of Experimental Medicine*, August 1, 1925).—The evidence offered in the studies indicative of a causative relationship between *Rickettsia ruminantium* and heartwater is supplemented by the following observations concerning the ticks which carry the disease. When larvæ, which had taken no food since hatching, were allowed to feed upon cases of heartwater, it was found they acquired rickettsiæ, which appeared to be identical with those in the tissues of animals suffering from heartwater, whereas control larvæ hatched from eggs deposited by the same female and fed on normal

animals, remained free of *Rickettsiæ*. After larvæ presumably infected had moulted the resultant nymphæ containing rickettsia in their alimentary tracts, when fed upon susceptible animals produced in them typical attacks of heartwater, which the control nymphæ, devoid of rickettsiæ, failed to do. The tissues of animals thus infected were found upon histological examination to contain typical rickettsia.

Studies on the Etiology of Heartwater. Observation of a Rickettsia, Rickettsia Ruminantium in the Tissues of Infected Animals (E. V. Cowdry, *Journal of Experimental Medicine*, August 1, 1925).—A Gram-negative, intracellular, coccus-like micro-organism was found in cases of heartwater in the three species which are susceptible to the disease, namely, goats, sheep and cattle. It was absent in the case of control animals, both normal ones and those dying of some other diseases. The presence of this micro-organism was definitely related to the febrile reaction. It was most easily detected in the renal glomeruli and in the small capillaries of the cerebral cortex, but probably occurred throughout the body. The micro-organism was a typical endothelial parasite, being restricted in distribution to the endothelial cells of the smaller blood-vessels and to portions of such elements which had broken off into the blood-stream. It was never observed to cause injury to the cells other than those incident to mechanical distension through accumulation within them of many individuals in large, densely packed masses which were characteristically spherical. A typical attribute was the presence of several of these masses within the cytoplasm of a single endothelial cell. In view of the association of this micro-organism with heartwater, a disease of ruminants, and thus far the only one in which micro-organisms resembling rickettsiæ have been reported, the designation *Rickettsia ruminantium* is proposed.

The Relation of the Vitamins to the Reaction induced by Coal Tar in the Tissues of Animals (Louis H. Jorstad, M.D., *Journal of Experimental Medicine*, August 1, 1925).—Drops of coal tar introduced into the subcutaneous tissue attract the fibroblasts, endothelial and other cells to them. These cells suffer degenerative changes through this action of the tar and the animal suffers cachectic-like changes and death from large doses of it introduced into the subcutaneous tissue. This action of the coal tar is limited to a short period of time, after which it becomes inert. The cells which have been drawn to it and which have not completely degenerated then slowly recover. Where large numbers of cells are drawn to the tar they grow and divide after recovering from the initial effects of the tar. Cancer may develop. Where only a few cells are drawn to the tar they lay down intercellular fibrils and a scar eventually develops. Vitamin A fed in more than ample quantities to these animals protects the animals and the cells against the toxic action of the tar and stimulates and prolongs their secondary growth. Vitamin B stimulates the secondary growth of these cells. This action is limited in extent and time. It is followed by an early degeneration and hyalinization of the tissue.

The Anticryptogamic Action of Fluosilicate of Soda and of Hydrofluosilicic of Acid in the Coagulation of India-rubber (A. Lambert, *Arch. des Instituts Pasteur d'Indochin*, April, 1925).—In the author's experience, the fungicide action of hydrofluosilicic of acid and of fluosilicate of soda is not sufficient to completely hinder the development of moulds; their development and fructification, however, are delayed. It is thought possible that in a "séchoir" where the conditions of humidity are less favourable, this delay can be sufficient for the humidity of the gum and the atmosphere to become such that the development of the moulds cannot be produced. The fungicide action of fluosilicate of soda is superior to that of fluosilicic of acid. The coagulation of the former by suspension in water is better than that obtained by powdered salt; with the latter method, the latex must be poured on the salt and not the salt on the latex. The chemical composition of the two samples of gum is much the same; only a slight increase in the ashes and a decrease in the resin are observed in the fluosilicate coagulated sample. The coefficient characteristics of each gum, vulcanized to the highest degree, are respectively 1·05 for the control coagulated with acetic acid and 0·91 for the control coagulated with fluosilicate of soda; the latter is therefore only worth 86·8 per cent. of the former. The coefficient characteristics, when the samples are old, are respectively: 0·66 when coagulated with acetic acid and 0·45 when coagulated with fluosilicate; the latter is only worth 67·6 per cent. of the former.

Tryparsamide Treatment of Neurosyphilis (Harry C. Solomon, M.D., and Henry R. Viets, M.D., *Journal of the American Medical Association*, August 1, 1925).—Serologic improvement has been marked in the majority of cases of all types of neurosyphilis treated with tryparsamide. In addition to the decrease in pleocytosis in the spinal fluid reported last year, reductions have been found in the Wassermann reaction, colloidal gold curve and globulin. Occasionally the spinal fluid has become normal after a few injections of tryparsamide, but in the majority of cases of parenchymatous neurosyphilis, fifty or more injections have been required to produce serologic improvement. Some cases, having received long courses of treatment with arsphenamin and other methods, without marked serologic improvement, have responded to tryparsamide. In general, in patients with neurosyphilis, more rapid and more marked clinical improvement has been observed under treatment with tryparsamide than with the older methods. Cases of early paresis have usually shown remission and have con-

tinued to hold their clinical improvement over the two-year period during which tryparsamide has been used. Clinical results have not yet been as good with the older cases of tabes with marked signs of degeneration of the spinal cord. Very few untoward symptoms, and none of marked importance have occurred in the last year. It has been found that it is often necessary to give tryparsamide over a period of a year or longer before either good serologic or clinical results can be expected.

Intarvin in Diabetes (Max Kahn, M.D., *Archives of Internal Medicine*, July 15, 1925).—The following results have been obtained through feeding intarvin to diabetic patients: It nourishes them so that they gain weight; it allays their sense of hunger. It strengthens them so that they do not feel so "weak and tired," the usual complaint of the diabetic patient. It never produces ketosis, i.e., beta-oxybutic acid, diacetic acid or acetone. It never produced acidosia. The latter has been determined in more than 100 cases by examination of the blood for the carbon dioxid combining power. It never yields glucose. Many more patients can be treated with intarvin and thus insulin can be preserved for the patients with very severe diabetes who really need it.

Abstracts.

HINTS ON TROPICAL TECHNIQUE.[1]

By ALEXANDER MARSHALL and NORMAN MACDONALD,
Wellcome Tropical Research Laboratories, Khartoum, Sudan.

In the tropics the difficulties of adhering to and following the general routine of laboratory technique must be experienced to be appreciated.

Methods as described in textbooks often prove quite unsuitable, and provide disappointing results when employed under tropical conditions. Modifications and improvisations are often necessary, as many adverse conditions present themselves. It is our aim in this series of notes to supply the laboratory worker in the tropics with some hints on laboratory technique, which we hope may be of practical value.

CLEANING GLASS APPARATUS, SLIDES AND COVER-GLASSES.

To clean laboratory glass-ware and render free from grease, place for one hour in a solution consisting of 100 grammes of caustic potash in 100 c.c. of water and 800 c.c. of methylated spirit, and afterwards rinse thoroughly in water. Cover-glasses should never be stored in a dry condition, but after cleaning should be kept in 60 per cent. alcohol. The cleaning solution can be used repeatedly.

[1] Abstract from the *Laboratory Journal*, December, 1924.

STERILIZATION OF SYRINGES BY BOILING.

It is important after sterilizing syringes by boiling to wash them out with a little sterile normal saline before taking blood. Very often a little water is left in the needle, and is liable to hæmolyse the blood.

TO STORE AND STERILIZE NEEDLES FOR BLOOD-LETTING.

A good way of sterilizing needles and keeping them ready for blood-letting for the Wassermann test, &c., is to obtain an ordinary glass xylol pot filled with absolute alcohol. Pass the needles, point downwards, through lengths of glass tubing, diameter about $\frac{3}{16}$ in., and a little longer than the needle. By placing the tubes with the needles suspended in them in an upright position in the pot of alcohol the points are preserved from injury. It is essential, before using a needle, to pass it through the flame and burn out the alcohol.

STORING AND STERILIZING GLASS CAPILLARY PIPETTES.

A very convenient way of storing and sterilizing capillary pipettes ready for use is to obtain a box made of zinc with square sides, dimensions 10 in. by 5 in. by 5 in., with a fairly tight-fitting lid.

Two square sheets of zinc, perforated with a number of holes of a size suitable for the pipette stems to pass through, and spaced so that the upper and wide ends of the pipettes can be comfortably arranged, are fixed inside the box one above the other. To accommodate pipettes 9 in. long, the lower plate should be fixed at a point 3 in. from the bottom of the box and the upper one about 2 in. from the top. The holes in the zinc plates should be directly opposite one another, so that the pipettes will stand in an upright position. The pipettes are then stored in the box with the capillary ends resting on the bottom and the whole sterilized by dry heat. To remove a pipette for use, place the box down on its side, thus eliminating the chances of aerial contamination.

TO STORE RUBBER TUBING.

As rubber tubing readily deteriorates in the tropics, store in glycerine (ordinary quality).

Another method is to store the tubing in bottles containing carbon dioxide gas. The tubing is coiled inside the bottles, which should be fitted with corks effectively sealed with melted paraffin wax, and having a central aperture sufficiently wide to allow the tubing to pass through. The gas is then passed through the tubing into the bottles, and the opening subsequently plugged with a piece of glass rod.

When a portion of tubing is required, withdraw what is wanted through the aperture in the cork, cut off and replace the glass plug in the open end of the tubing left protruding from the cork.

Hydrogen-ion Concentration Method of Standardizing Media.

The reaction of any fluid is determined by the relationship between the hydrogen- or hydroxyl-ions present in it, expressed symbolically as pH.

A neutral fluid is one in which the concentration of hydrogen-ions is the same as hydroxyl-ions, and at 21° C. is expressed as pH 7. If the pH is less than 7, the fluid is acid; if the pH be greater than 7, it is alkaline. For bacteriological purposes, a range between pH 7·4 and pH 7·6 is usually employed.

The solutions required are: I.—A one-fifth normal solution of dihydrogen potassium phosphate. This is made by weighing out 13·616 grm. of the salt and dissolving it in about 300 c.c. of boiled distilled water. The mixture is then made up to 500 c.c. with boiled distilled water. II.—A N/10 solution of sodium hydroxide.

From these two solutions the following mixtures are made up:—

N/5 KH_2PO_4	N/10 NaOH	Water to	pH
25	17·80	100	6·6
25	23·65	100	6·8
25	29·63	100	7·0
25	35·00	100	7·2
25	39·50	100	7·4
25	42·80	100	7·6
25	45·20	100	7·8
25	46·80	100	8·0

A grain of calomel is added to these solutions to prevent bacterial growth.

Cordite tubes (as supplied by Baird & Tatlock) are then filled with the above solutions, adding 10 c.c. to each tube and 0·4 c.c. to each tube of a 0·02 per cent. solution of phenol red. The tubes are then set out with the proper pH indicated upon them, and should be kept in the dark when not in use. It is advisable to fill the tubes once a month from the stock solutions, as the phenol red is liable to fade after that time. The 0·02 per cent. solution of phenol red is prepared by dissolving 0·1 grm. of phenol sulphonephthalein in about 100 c.c. of distilled water, to which 10 c.c. of N/10 sodium hydroxide solution have been added. About 300 c.c. of water are added, and the alkaline solution of the indicator is exactly neutralized with 10 c.c. of N/10 hydrochloric acid. The volume is then made up to 500 c.c.

Method.—10 c.c. of the medium is measured into one of the cordite tubes, and 0·4 c.c. of the 0·02 per cent. solution of phenol red is added. This tube is put in place 5 of the viewing rack. In places 4 and 6 are put the standard tubes of the reaction between which it is desired to adjust the medium. In place 2 is put a tube of distilled water. In places 1 and 3 are put tubes containing the medium without the addition of indicator.

In this way the light passing through the standard tubes 4 and 6 traverses tubes containing uncoloured medium 1 and 3, while the tube containing medium and indicator in 5 is backed by a column of water. The conditions under which the light comes through the columns of liquid in all three sets of tubes are thus identical.

With a 1-c.c. pipette graduated in 1/100ths, drop in N/10 NaOH to tube containing the medium until the tint comes between the tints on either side of the pH required. After the addition of each small quantity of N/10 alkali the contents of tube 5 are well mixed before comparison.

Knowing the amount of N/10 alkali which is necessary to bring the contents of tube 5 to the required tint, it is easy to calculate how much decinormal alkali will be necessary to bring a large volume of the medium to the requisite hydrogen-ion concentration.

To make a viewing box for the above method, obtain six square wooden test-tubes boxes suitable for carrying test-tubes 6 in. by 5/8th in. Pierce a round hole about 5/8th in. in diameter through the centre of the lower third of each. Place the boxes together so as to form one block with the view holes directly opposite one another. Bind the whole with black paper, leaving the view holes open. Number the boxes from left to right, 1 to 3 behind and 4, 5, 6 in front.

Culture Media.

In the preparation of media, all methods of sterilization must be carefully carried out, as the presence of moulds, aerial and dust organisms (many of them spore-bearing) are a frequent cause of contamination. In a tropical climate, moulds of a highly resistant type often grow on the under-surface of cotton plugs, and to obviate this, it has always been our practice to carry out a preliminary sterilization of the cotton in the hot air chamber for 1½ hours at 150° C. before using it for plugging tubes.

It is advisable to sterilize all media in the autoclave; one sterilization at 15 lb. pressure for a period of fifteen minutes is, we find, much more satisfactory and quicker than the three consecutive sterilizations in the steamer.

Filtration of Agar.

After autoclaving allow the flask of agar to stand for five minutes to permit the coagulated elements to settle, and filter through glass wool. It is unnecessary to heat the funnel, as filtration of the agar is so rapid that in ten minutes a litre of clear agar will be obtained. It is as well to mention here that we add 2 per cent. agar to our media, as a firmer consistency is required than that used in a temperate climate.

Carbohydrate Media.

In the preparation of carbohydrate media we carry out the following procedure: Make a litre of lemco meat extract broth in the ordinary way and render pH 7·6. After boiling, allow to stand until the phosphates have precipitated. Filter and adjust the pH.

Next add the required percentage of Andrade's NaOH fuchsin indicator and 1 per cent. of the sugar to be used. Tube and sterilize in the autoclave at 15 lb. pressure for ten minutes. This

heating is not always sufficient to drive the air completely out of the Durham's tubes; therefore, a preliminary heating in the steamer for five minutes at 100° C. is recommended.

We find the above to be a very satisfactory method, as it sterilizes the media completely and reduces to a minimum hydrolysis of the carbohydrates which is known to take place when overheated in the presence of peptone and other proteins.

C.R. Milk.

We prefer to add C.R. indicator to our milk instead of litmus as it stands autoclaving very well and remains unaffected by the climatic conditions.

Indicator.—Equal parts of a 1 per cent. watery solution of China blue and 0·5 per cent. solution of Rosolic acid in 95 per cent. alcohol.

To prepare C.R. Milk.—Steam fresh milk for fifteen minutes and place on ice-chest for eight hours, or better still, centrifugalize for fifteen minutes. Separate cream and dilute milk one-third of distilled water. This facilitates heat penetration during sterilization. The C.R. indicator is added in the proportion of 2·5 per cent. Boil milk for five minutes, tube and sterilize. If the medium appears too acid, the reaction is adjusted till a pale grey colour is obtained. Blue indicates acid and pink alkali.

Loeffler's Blood-serum.

In the preparation of this medium the intermittent method of sterilization is best avoided. Not only is it a slow process, but in the tropics, where blood-serum cannot always be procured in a sterile manner, the possibilities of the growth of aerial and dust organisms in between the periods of sterilization are great. To overcome this difficulty, we inspissate the tubes of media from eight to ten hours, raising the temperature gradually until it reaches the maximum of 70-75° C. If the inspissation cannot be carried out on the one day, the medium can be exposed to the maximum temperature for the remainder of the period on the day following. If this is done, it is advisable to place the tubes of media in the ice-chest overnight. The idea is to coagulate the serum slowly, and thoroughly, so that no soft parts will be left to bubble their way through the body of the medium and break up the surface of the slopes during sterilization. The tubes of media are finally sterilized in the autoclave at 15 lb. pressure for ten minutes. By this method the finished medium is highly satisfactory in every way, and equally as good as that prepared by the tedious intermittent method.

Sabouraud's Maltose or Glucose Agar for the Cultivation of Fungi.

We recommend the above medium as being most suitable for the cultivation of fungi. To prepare this medium, first of all make up the agar in the ordinary way, and after filtration add the percentage of sugar required, tube and sterilize in the autoclave at 15 lb. pressure for fifteen minutes. It is essential to add the sugar to the prepared agar, otherwise the prolonged heating of the two combined affects the solidifying properties of the agar. Preserve the water of condensation in the agar slopes as moisture is most necessary for the cultivation of fungi.

Horse-dung Agar.

This is a highly suitable medium for the cultivation of fungi. Dry horse-dung 200 grm., water 1,000 c.c., infuse for twenty-four hours. Filter through muslin, then through filter paper without neutralizin. Add to 500 c.c. of above: peptone 5 grm., agar 10 grm. Sterilize for twenty minutes at 120° C. Filter; add glucose 20 grm. Tube and sterilize for ten minutes at 115° C.

McConkey's Bile-Salt Lactose Agar.

For the isolation of intestinal bacteria such as organisms of the typhoid and dysentery groups by plate culture, we recommend the above medium. We have tried most of the other media recommended for this work, and find McConkey's agar the most reliable. It is easy to prepare, and stands the tropical heat exceptionally well. On adding the neutral red to this medium, we find it more expedient to add 0·05 grm. of the powder per litre direct, instead of the usual process of making up a 1 per cent. solution and adding from this 0·5 per cent. The neutral red powder is dissolved by stirring vigorously in a mortar containing about 200 c.c. of the hot medium. Our reason for doing this is because the neutral red does not keep for any length of time after being made up.

It is advisable to pick off any apparent non-lactose fermenting colonies that appear on the plate culture of the medium, and transfer to a tube of lactose broth, as late lactose fermenters often remain colourless for two to three days on the solid medium, but readily show fermentation in the fluid medium.

We recommend the following media for the growth of the more delicate bacteria: *Gonococcus*, Cole's blood-agar; *Streptococcus*, Holman's broth; *Meningococcus*, Buchanan's solidified blood-serum; *Pneumococcus*, whole blood-agar.

Blood Culture.

Three sterile broth flasks of a pH 7·6, and containing 100 c.c. of medium in each, plus a few glass beads, are used. Withdraw 7 c.c. of blood from a vein in the arm, and add 2 c.c. to each of the flasks. Rotate the flasks immediately after inoculation, so that the beads contained in the medium will defibrinate the blood. Incubate at 37° C. for forty-eight hours, then put up an agar slope from each.

Storing of Media.

In the hot seasons of the year, culture media are very apt to become desiccated owing to the evaporation of the water of condensation. This can be prevented to a great extent by storing the tubes of media in circular glass jars with zinc lids. A ring

of plasticine is inserted inside and round the periphery of the lid; the layer of plasticine must be sufficiently plentiful to allow the opening of the jar to be effectively sealed when the floor of the lid is pressed down. The advantage of the method is, that as each worker withdraws a tube from the jar, the lid can be easily and readily sealed again by simply pressing down the lid.

McConkey's Agar for Out-stations.

Occasionally requests are received from medical officers at out-stations for a supply of McConkey's bile-salt lactose agar plates. If the medium is to be forwarded by post, it is advisable to send it contained in flasks of 100 c.c. capacity, accompanied by sterile Petri dishes wrapped up in filter paper. Instructions to pour the medium into the plates, taking the usual aseptic precautions, should also be enclosed.

Sending Fluid Media in Flasks by Post.

To obviate the risks of contamination of fluid medium forwarded by post we find it expedient to seal the flasks with surgical oiled silk instead of the usual cotton-wool plugs. The oiled silk should be sufficiently large to be turned down and fastened by a few turns of thread round the neck of the flask and under the lip. The flasks of media are then sterilized in the autoclave at 15 lb. pressure for twenty minutes. On cooling, the silk covering is pulled taut by the contraction of the fluid and air within. The silk is then smeared over with melted paraffin wax, and a perfectly air-tight covering is obtained. To inoculate the flask, heat the surface with a hot sterile knife or other suitable implement; pierce the covering with a syringe needle, and squirt the syringe contents into the medium. Withdraw the syringe needle and close the puncture by melting the paraffin again with the hot sterile instrument.

The method described is much more serviceable and permanent than the use of rubber caps or corks, and certainly more economical.

Despatching Blood Films by Post.

Pack the films together with intervening bits of cardboard to prevent the slides from rubbing. Roll them up in good strong white paper. Seal the ends of the packet with sealing wax; then drop into a vessel containing melted paraffin. Leave in the paraffin just long enough for the packet to become permeated with the wax. This method will preserve the smears for an indefinite period and prevents the growth of fungi, which are so troublesome to workers in the tropics.

The Keeping of Stock Cultures.

Rubber caps being out of the question in the tropics owing to their perishable nature, a clean and economical way of sealing stock cultures is by the use of thin, white paper and melted paraffin; thin typing paper is the most suitable. A square of paper slightly larger than the diameter of the culture tube is cut, and a layer of melted paraffin spread over it with a small brush. Next flame the outside of the cotton plug and push it slightly below the level of the top of the tube. Warm the top of the tube a little, and placing the paraffined paper over the opening, apply gentle pressure with the palm of the hand until the paraffin sets. Next take a glass slide and scrape away the surplus paper round the tube opening. It is as well to paint over the outside of the paper covering again so as to strengthen the surface. Should the tube be required for subculturing, it is a simple matter to flick away the paper with the point of a pair of forceps.

Collection of Stools for Microscopical Examination.

A suitable improvised means of sending stools to the laboratory for examination is to obtain the tin covering of crown head corks from soda water bottles. Remove the disc of cork and punch two small holes in the rim about $\frac{1}{4}$ in. apart. Pass an ordinary hair-pin of stout quality through the holes from without inwards, bend the loop end over and inwards to form a grip. Next bend the prongs of the hair-pin upwards and backwards until they are at right angles with the crown head cover. Finally press the turned-over loop and prongs of the hair-pin firmly against the rim of the metal cover with a pair of pliers, and a firm grip will result. The scoop is best contained in a glass sample tube $2\frac{1}{4}$ in. by $1\frac{1}{2}$ in., and is fixed by simply pushing the hair-pin ends into the lower part of the cork.

Picric Acid as a Fixing Reagent.

A saturated watery solution of picric acid (1 part in about 86 parts of water dissolved at 15° C.) has been used by us for many years as a fixing reagent for skin and dense fibrous tissues. It has the advantage that no excessive hardening takes place as the result of the fixation, which is effected in from one to several hours, according to the nature and size of the piece of tissue. After fixing, the tissue is washed in running water for several hours and carried through to paraffin in the usual manner. Although it has been stated that the gradual weakening of the picric acid by water, even when used in the composition of the stains, tends to disintegrate the tissues, we have failed to notice any disintegration even after washing the tissue in running water for twelve hours and using watery stains on the sections.

Museum Jars.

Owing to the intense heat during the summer months in the tropics, great difficulty was experienced with regard to museum specimens. Not only the lids would crack, but even the jars themselves. Various cements were used in the sealing of the lids to try and overcome this difficulty, but without success. Finally, we resolved to allow for expansion and contraction by drilling a very small hole in the lids of the jars. In some cases we sealed the hole thus made with a thin cover-glass and

Canada balsam; in others, the hole was left open and no appreciable evaporation of the fluid was noticed. The method seems to be a solution of the difficulty, as the jars and lids, without exception, have withstood the rigours of a tropical summer.

Vaccine Caps.

The rubber caps of bottles containing vaccine are best coated with a wax of low melting point, as we find that the ordinary paraffin used for section cutting (m.p. 56°-60° C.) cracks and flakes off, leaving the rubber exposed.

Widal's Agglutination Test.

Garrow's agglutinometer is an ideal instrument for the above test, and no worker in the tropics should be without one.

Cooling of Water and Solutions for Photography.

Photography in the tropics, in a close, hot, dark room, is a trying experience, and even although one starts off with ice-cooled solutions, they very soon become warm. If a good table electric fan is available, there is no necessity for using ice at all. A better way is to set the dishes containing the solutions in a line in front of the electric fan. Let the fan play on the dishes, and in about ten minutes the solutions will become quite cold and will remain at a suitable temperature for any photographic plate or film, and, moreover, the photographer enjoys its cooling properties on his heated brow.

Ice-Chests.

All ice-chests with doors opening in the side and where the ice is contained in a jacket round the chamber require a great quantity of ice to keep them really cold, and every time the door is opened the temperature of the chamber is raised considerably. A cheap and economical ice-chest may be made by using two large square wooden boxes, the inner one lined with zinc and of suitable size to leave a space of about four inches all round between it and the outer box. This space is tightly packed with sawdust, old blankets, charcoal, or cotton. The lid opening on the top is also packed, lined with zinc, and should be fairly tight-fitting. An ice container is made by cutting in half an ordinary kerosene or petrol tin and of suitable size to go inside the inner box. This tin is easily removed and the water emptied when fresh ice is put in.

Current Literature.

Bulletin de la Societe de Pathologie Exotique. July 8, 1925.

Eparseno or Dr. Pomaret's "132" in the Treatment of Leprosy (F. van den Branden).—This arsenical has already been used in the treatment of leprosy by Chartres and Hasson with very good results. Hasson used massive doses by intramuscular injections daily, but the author found in following this method that phenomena of intolerance were shown by the patients, such as loss of weight, general malaise, neurotic pains, inappetence, &c. The product causes clinical ameliorations; cicatrization of the ulcers, change in colour of the muscular lesions, but they are only of short duration; new cutaneous lesions have been observed in a leper after long treatment with eparseno.

Culture of Entamœba dysenteriæ by the Method of Boeck and Jaroslav (F. H. Guerin and R. Pons).—*Entamœba dysenteriæ* was cultivated by Boeck and Drbohlav (1924) at Boston, U.S.A., on a medium of coagulated egg and Ringer's solution albuminized. These observations confirm the results obtained at Boston, and also give definite points on the technique of the cultures. It is proved that dysenteric amœbæ can be cultivated in the presence of only one microbic germ by experimental selection, as was discovered by Gauducheau for *Endolimax phagocytoides* (1908).

Batrachia which Harbour and Propagate certain Intestinal Flagella of Man (E. Escomel).—On examining batrachia taken from rivers and drinking water sources of Arequipa the intestinal tract was found to contain numerous protozoa. When the animals are taken out of the water, and the water is centrifuged, large numbers of *Trichomonas batrachorum*, *Opalina ranarum*, *Nyctoterus*, *Monadina*, *Amœbæ* and other protozoa are found. These protozoa multiply in the intestine of the batrachia in very large quantities, and are expelled alive into the water and damp earth. Experiments show that the protozoa soon die if deprived of nourishment. It is therefore most necessary that all drinking waters should be cleared of these animals, and also of seaweed, which serves as nourishment to the protozoa.

Presence of Rhabditis Larvæ of Strongyloides stercoralis (Bavay, 1877) in Duodenal Liquid taken by Tugaba. Clinical Notes on Anguilluliasis (R. Deschiens and O. Taillandier).—Rhabditoid larvæ were found in the duodenal liquid taken from a patient of Haiti presenting *Strongyloides stercoralis* in the stools. The larvæ were 200-300 microns in length and 14-17 in width. The patient had been infested for seventeen years; he had attacks of diarrhœa, digestive troubles with duodenal ulcer syndrome, and was neurasthenic. The duodenal lesions of anguilluliasis and the possible duodenal ulcer syndrome were detected by X-rays.

Notes on an Epidemic of Bacillary Dysentery in Mayombe (Belgian Congo) (L. Van Hoof).—Bacillary dysentery occurs sporadically all over the Congo, but in places where hygienic conditions are not satisfactory it takes on an epidemic form with sometimes a very high mortality. The malady in its epidemic form has been observed at Mayombe during the past few years among the different tribes. Famine is the first and foremost of the causes of the disease, which very often takes place during the months of September and October. Transport

by caravans, &c., is another means of transmitting the disease. Helminthiasis and intestinal amœbiasis frequently coexist with bacillary dysentery, thus rendering diagnosis and treatment difficult.

Parasitism and Morbid Reactions in Chronic Malaria in Native Children of Algeria (H. Foley, A. Catanei, M. Brouard and P. Demimuid).—In the Tell region, amongst the Arabs, the splenic index is always higher than the plasmodic index. The three species of plasmodium are found, alone or, rarely, associated. The chief vector of malaria is *Anopheles maculipennis*. At Beni Ounif-de-Figiug, and in all the cases of northern Sahara, where the population is mixed, the splenic index is always very inferior to the plasmodic index. The seasonal plasmodic index is much less than the annual index, which accounts for the frequent absence of *Plasmodium*. The infection is frequently found in children of all ages up to ten years, it gradually decreases up to fifteen years, and after that age is very rare. In certain adults, white race, *Plasmodium* are found in the blood, although all clinical symptoms are absent. The association of *P. vivax* and *P. præcox* is very frequent.

Anopheles multicolor is the vector of malaria in all the Algerian Sahara.

The Action of Stovarsol in Chronic Malaria due to Plasmodium vivax in Native Children in Algeria (H. Foley, A. Catanei, M. Brouard and L. Leblanc).—Stovarsol administered *per os* has given very good results in the treatment of chronic malaria; it causes no reactions and is well tolerated even in large doses. In two to three days it causes the disappearance of all *Plasmodium vivax* from the peripheric blood.

Notes on Malaria at Tangiers during the Last Twenty Years (H. Charrier).—The statistics of the French Hospital at Tangiers show that malaria has been on the increase during the past twenty years; this is probably due to the extension of the town towards the sites of *Anopheles*. As regards nationality, the Arabs furnish most cases of malaria; this, no doubt, is due to their occupations, while there are very few cases among the Jews. Among Europeans malarial cases are to be found chiefly in the Spanish people. The climate at Tangiers is most favourable to the evolution of the hæmatozoa of mosquitoes during six months of the year, i.e., May to October; the rains, winds and humidity also have an influence on the life-history of mosquitoes and on their power to transmit infection.

Human Intestinal Coccidiosis due to Isospora belli (*Wenyon* 1922). *General Observations. Study of Two New Cases observed at Saigon* (R. Pons).—A very interesting account is given of the history, geographical distribution and morphological characters of intestinal coccidia. An accurate diagnosis can only be made by microscopical examination; the stools will be found to be rich in oöcysts of coccidia; attention is drawn by the presence of the sporoblast, spherical, granulous mass, and the enveloping membrane.

Communication on the Nature of the Epidemic of Glossitis observed in Senegal (C. Mathis and Guillet).—This epidemic of glossitis broke out among the school children of Dakar during the months of February to April, 1925. There were six principal types observed, but the bacterium to which the disease was due has not yet been completely identified. As the epidemic is seasonal in Senegal, there may be further possibilities of carrying out researches.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments**, either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum**, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

Original Communications.

PHOSPHORUS IN THE TREATMENT OF VARIOUS DISEASES.

By ALDO CASTELLANI, C.M.G., M.D., F.R.C.P.

Director of Tropical Medicine, Ross Institute and Hospital, London; Lecturer London School of Tropical Medicine.

PHOSPHORUS at one time was considered to be of great benefit in various diseases, especially diseases of the nervous system (paralysis agitans, locomotor ataxy, impotency of various origin); it was also used in the treatment of leukæmia, pseudo-leukæmia, chronic tuberculosis and osteomalacia. Later its use was practically abandoned, this being caused, to a great extent, by difficulty in finding a stable preparation to be given by the mouth.

For some years I have been interested in phosphorus as a therapeutic agent since I found that the drug in the form of Oleum Phosphoratum of the British Pharmacopœia can be given subcutaneously by hypodermic injection, causing very little or no discomfort. In this paper I will briefly recapitulate my results with phosphorus in various diseases.

Preparation of Phosphorus Used.—The preparation I have used, both for external and subcutaneous use, is the phosphorus oil of the B.P. Messrs. Martindale and Co., at my suggestion, supply it now in very convenient ampoules of two kinds; ampoules containing 5 minims of pure phosphorus oil, and ampoules containing ½ minim diluted in 10 minims of almond oil.

Oriental Sore (Cutaneous Leishmaniasis).

I have published several papers on the treatment of oriental sore with phosphorus, which I introduced in 1923. The results seem to be in most cases satisfactory; the best results are obtained in old intractable cases in which the ulcerative process is extensive. The technique of the treatment is as follows: when the ulcerative process is well marked, the oil is simply dabbed on the fundus and margin of the sore, after removing the scab, every other day. When the ulcerative process is not well developed, and the lesion is nodular, in addition to the external use of the oil 3 to 5 minims of it are injected by means of an all-glass hypodermic syringe under the skin around the nodule, and at times also into the nodule, once or twice a week, according to the reaction caused. The actual injection is practically painless. As a rule there is no general reaction; the local reaction is often slight, but occasionally signs of acute inflammation develop; in such cases the treatment is discontinued for a time and hot boric fomentations are applied.

Granuloma Inguinale.

Recently I have had two cases of granuloma inguinale in which the tartar emetic treatment induced only a slight improvement. One of the patients, a South American, had contracted the disease in Central America. The lesions, situated in the left inguinal region, though not of great extension, were typical, and scrapings contained Donovan bodies in abundance. Wassermann was negative. The ulcerations were thoroughly cleansed with boric fomentations for two days, and then the phosphorus treatment was started. This consisted in the simple application all over the ulcer of phosphorus oil every other day. Within six weeks the ulceration healed completely. In the second case, a half-caste who contracted the disease in the West Indies, and who had ulcerative lesions in both inguinal regions, the phosphorus treatment had no beneficial action.

Tropical Sore.

In a case of very chronic tropical sore of the leg, in a Ceylon planter, the phosphorus oil did not induce any improvement.

Psoriasis and Lichen.

I have tried phosphorus in several cases of psoriasis and lichen planus with no beneficial results.

Malaria.

Phosphorus alone has no effect on the malaria parasites; in certain very chronic cases of the disease it seems, however, to act as a good adjuvant of quinine. It is given subcutaneously in very small doses, half minim to three minims of the phosphorus oil twice a week.

Other Diseases.

Some years ago I used phosphorus oil in several cases of rickets and in two cases of osteomalacia with encouraging results. I have also used it in cases of tropical neurasthenia and impotency with, however, no very brilliant results.

In a case of beri-beri a distinct improvement took place.

Conclusions.

Phosphorus seems to be useful in various diseases. The preparation of phosphorus I have used is the phosphorated oil, B.P., which some years ago I found could be given by hypodermic injection with very little or no discomfort to the patient. In certain cases of oriental sore it acts practically as a specific. Of two cases of granuloma inguinale one responded to the phosphorus treatment, the other did not. It seems to be useful as an adjuvant of quinine in certain cases of chronic malaria, and its action also seems to be beneficial in osteomalacia and rickets.

Phosphorus is a powerful drug and its delayed action on the liver should especially be kept in mind; it should therefore be given with care and every precaution should be taken. I may say, however, that so far in my hands its use has never been followed by any untoward effect.

A NOTE ON THE TREATMENT OF AMŒBIC DYSENTERY WITH STOVARSOL.

By F. M. Johns, M.D.,

AND

S. Chaille Jamison, M.D.

From the Department of Medicine, Tulane University School of Medicine, New Orleans.

Dr. E. Marchoux reported in the official *French Bulletin of the Société Pathologie Exotique* [1], February, 14, 1923, the eradication of *Entamœba dysenteriæ* cysts which had persisted in a patient following the clinical cure of his dysentery with emetine, by the use of stovarsol (oxyaminophenylarsenic acid). Doses of 0·25 grm. were administered by mouth twice daily until twenty successive doses were given. Three cases of *E. coli* infection were similarly sterilized. Remarkable clinical results were also reported in chronic amœbic dysentery, but these were followed by relapse in from ten days to three weeks.

This publication by Marchoux was soon followed by one by Nogue and Leger [2], who reported three cases treated, one of whom relapsed nine days later and had to be treated with emetine.

Delanoë [3] reported the rapid clinical cure of two cases, one of which was of four years' duration. Subsequent observation was not reported.

At the Conference on Tropical Health Problems held in Kingston, Jamaica, in July, 1924, Drs. Ch. Garin and P. R. Lepine [4] reported the use of stovarsol followed by hypodermic administration of emetine or of acetylarsan, in a series of forty cases of amœbiasis. No detailed studies of the effect of stovarsol alone were given and the number of ultimate cures was not tabulated; neither was the length of time stated that patients had been observed.

Dr. Lepine kindly furnished one of us (Johns) with enough stovarsol (through the courtesy of the manufacturers, Poulenc Frères, Paris) to treat several cases of dysentery. A larger quantity of the drug has been furnished for experimental purposes by Messrs. Powers, Weightman and Rosengarten, of Philadelphia.

Up to the present time we have treated twenty-seven cases of amœbic dysentery with stovarsol. The results have been so remarkable that we feel justified in making this preliminary report. The cases have ranged in severity from chronic dysentery of long duration to active, severe, emaciated clinical cases. The duration of the disease has ranged from a few weeks to as long as twenty-five years. Diagnosis was confirmed in all cases by the presence of endamœbæ in the stools or in scrapings obtained through the proctoscope and was always verified by the use of wet fixed preparations stained by the iron-alum-hæmatoxylin method of staining the nuclear structure.

In all instances (except one patient that received a smaller amount) stovarsol in 0·25 grm. doses administered three times daily for one week caused complete subsidence of their symptoms, the improvement usually beginning about the third or fourth day of treatment.

The first case treated was found to have developed encysted entamœbæ on the fifteenth day following stovarsol treatment, in spite of the hypodermic administration of emetine during the interval. The fourth case presented a clinical relapse on the sixteenth day, vegetative entamœbæ being found in the semi-liquid stool.

Three cases remained well and free from entamœbæ up to the present time upon the one course of treatment. Two of these received seven ½-gr. doses of emetine, which was hardly sufficient to account for a cure by itself. These patients have been under observation for ninety-nine, seventy-four and seventy days, respectively.

The remaining cases have received a second course of stovarsol seven to ten days after the first and consisting of three 0·25 grm. tablets per day for seven days, or two tablets for twelve or fourteen days.

Up to the present time (January 20, 1925) we have been able to follow with clinical, proctoscopic and microscopic examination twenty cases for an average period of fifty-five days following completion of their treatment. Sixteen cases have remained well and free from entamœbæ for the period of observation.

Four cases have relapsed; three of these clinically, and one developing cysts. The clinical relapses occurred within two weeks and were noted in patients having had dysentery for three to five years almost continuously. It must be noted, however, that the lesions as found by proctoscopic examination had subsided to a remarkable degree, a single rectal granulation the size of a silver dollar in one instance and pin-point ulcerations in the other.

Many of the apparently cured patients have been proctoscoped, and stool examinations were repeatedly made, all with negative findings. It has been our experience that vegetative entamœbæ can be demonstrated by proctoscopic examination of the rectum or cysts can be found in the formed stools within twelve to fifteen days following completion of a course of treatment of whatever kind in practically all cases that subsequently relapse. This experience leads to the hope that these cases treated with stovarsol, and which are still free from symptoms or entamœbæ, may be permanently cured of their infection.

Long standing cases with massive involvement of the bowel walls present the same difficulty of treatment that applies in other tissue-invading parasitic diseases, the parasites being protected by impermeable walls of exudate and tissue proliferation. Indeed, it is evident that no known specific will cure in all instances. It is hoped, with the establishment of definite knowledge regarding the tolerance for this drug when given over longer periods of time than we have dared employ it, that the results will be even better than are here indicated.

Stovarsol (acetyloxyaminophenylarsenic acid, or "190") is an arsenical designed by Levaditi and Navarro, to be administered through the digestive tract. It was synthetized by Fournier, Guenot and

Schwartz [5] and has been the subject of considerable European investigation in the treatment of syphilis. It is apparently partly absorbed from the small intestine and then excreted through the large intestine. It is relatively non-toxic. The only untoward effect attributed to it that we have found was a dull headache in one instance, mild rash in another and probably a rash with slight temperature in a third case.

We have not attempted to determine the proper dosage of stovarsol, but the following observations may be mentioned:

Quarter gramme per day in one case failed to influence the symptoms to any great extent in seven days.

Half gramme per day has given favourable results in two subacute cases.

Three-quarter gramme per day for seven-day periods has shown the most uniform results in the first course.

It will be necessary to follow these and other cases for a considerably longer period of time before we will know whether the apparent cures are complete or whether they are temporary. It is our intention to report more fully on these and other cases treated subsequently after a sufficient number have been under observation a sufficient length of time to determine the permanency of the results.

In the meantime, our experience so far indicates that we have in stovarsol a supposedly harmless remedy for amœbic dysentery that compares quite favourably with anything previously employed.

We desire to express our thanks to the following doctors for their assistance in referring cases and in the observation of this work: Drs. E. D. Martin, J. B. Elliott, H. E. Nelson, J. E. Landry, M. Bradburn, E. Bass, J. C. Cole, P. J. Kahle, J. Lescale, G. S. Bel, J. H. Smith, A. L. Levine, L. J. Stookey, A. M. Parson, and F. Loria.

REPORT ON A FATAL CASE OF BACILLARY DYSENTERY IN NIGERIA.

By Andrew Connal, M.D., D.P.H., D.T.M.&H.,

AND

E. C. Smith, M.D., D.P.H.

From the Medical Research Institute, Lagos.

This report gives the clinical history, along with the bacteriological and post-mortem findings, in the first case of bacillary dysentery recorded from Nigeria.

Although the usual routine examination of dysenteric stools has been a regular procedure at the Medical Research Institute since its establishment, it was not until 1918, with the return of native troops and carriers from the East African campaign that it was decided to investigate fully and systematically all cases of dysentery occurring in Lagos. Special efforts were then made to secure freshly-passed stools from all patients.

Previous to the present case, the search was successful on only one occasion. In this instance, during 1920, a bacillus of the Flexner type was isolated from a case of amœbic dysentery, which occurred in a war veteran who had served in several countries where bacillary dysentery existed. There were, however, abundant *Entamœba histolytica* in the stools, the attack responded quickly to emetine treatment, and it was concluded that the patient was probably merely a carrier of the bacillus. Apart from this case, the search, continued practically uninterruptedly and by several workers during the past seven years, has been unsuccessful.

So far as can be ascertained, no bacteriologically confirmed case has been reported from the Gold Coast or from the Gambia. Sierra Leone, however, furnished a number of cases in 1919, as recorded by Butler [1].

A study of the annual medical and sanitary reports from the four West African colonies under British administration, shows that in some instances the dysenteries are classified as "amœbic," "bacillary," and "type undetermined." The diagnosis of "bacillary" is a clinical one. In general, it may be said that the mortality is not such as to indicate a bacillary form of the disease and there are no histories of epidemics. While it cannot be stated that bacillary dysentery does not exist, it may be asserted that the infection is uncommon. Nevertheless, so far as one can judge, the conditions, climatic and otherwise, are not unfavourable to endemicity, and it is for this reason that continued investigation is required.

It should be added that, in certain parts of Nigeria, schistosomiasis causes dysenteric signs and symptoms.

Present Case.

The patient, a male adult, native of Lagos, was admitted to the African Hospital under the care of Dr. C. J. H. Sharp, M.C., by whose kindness the investigation was assisted. On admission on August 5, 1925, the patient complained of dysenteric symptoms which had begun five days previously. He was put upon emetine and an examination of the fæces was made. The stool consisted of liquid bile-stained fæcal matter, showing flecks of bloody mucus. Under the microscope no amœbæ, cysts or spined ova were seen.

A loopful of the blood-stained mucus was mixed in 10 c.c. of peptone and after two hours this was inoculated on MacConkey plates. After twenty-four hours' incubation, colonies of a non-lactose-fermenting organism were obtained.

The organism was Gram-negative, non-motile and fermented mannite and glucose without gas-formation. It did not produce indol in broth cul-

ture. The patient's serum gave a rapid naked-eye slide agglutination with a known Flexner type of organism. Agglutination with a known Shiga and a known Y type also took place, but was much slower and less marked.

The patient rapidly became worse and died two days after admission.

Post-mortem Findings.—The post-mortem was made four hours after death.

Macroscopic.—The body showed marked general wasting and retraction of the abdominal wall.

Abdomen.—No fluid exudate was observed in the peritoneal cavity, but patches of fibrinous material were present here and there on the surface of the intestines and liver. The spleen was greatly enlarged and exhibited marked capsular thickening. The organ was very firm in consistence. The liver was darker in colour than normal and the lobulation was hard to distinguish in cut surface.

The kidneys presented a striking appearance—that of a typical blood-infection. These organs were very congested and were diffusely sown with small abscesses, each about the size of a pin-head, but varying in places owing to fusion. On removal of the capsule, many of these were broken into. Smears made from the contents revealed the presence of numerous polymorph cells and Gram-negative bacilli. No distension of the renal calyces or ureters was present.

The bladder contained a quantity of cloudy urine and the wall of the organ was covered with a fibrino-purulent exudate.

The stomach showed nothing of interest. In the small intestine inflamed hæmorrhagic patches occurred towards the lower end of the ileum. The colon, from the cæcum downwards, presented here and there irregular ulcerated areas intermingled with patches of hæmorrhage. The ulcerated areas were definitely patchy and not very extensive. A general enlargement of the mesenteric glands was found. They were soft and œdematous.

Thorax.—No pleural effusion was present. The lungs were congested and delicate fibrous adhesions occurred on both sides. The heart-muscle was flabby, but no valve-lesion was found.

Broth cultures were made from the heart's blood, the gall-bladder contents, the urine and the contents of the colon. A pure culture of a non-lactose-fermenter was obtained from the urine, the gall-bladder and the colon. This organism possessed similar properties to that obtained ante mortem from the stool.

Pathological Histology.

Intestinal Tract.—The lower portion of the ileum showed considerable vascular congestion with exudation, mainly of polymorphs, but also of round and plasma cells into the mucous membrane. In the colon a similar condition was present in a more marked degree, the mucous membrane in places being entirely replaced by the inflammatory exudate. Patches of a fibrino-purulent membrane occurred on the surface of the inflamed mucosa. In this membrane the polymorph cells predominated, but lymphocytes, plasma cells and red blood cells also took part in its formation. The submucous coat showed marked œdema and diffuse inflammatory infiltration. Small groups of inflammatory cells were also to be seen between the separated muscle bundles of the circular and longitudinal coats.

Mesenteric Glands.—The vessels in the capsules of these glands were congested and surrounded by halos of exudated cells. The gland tissue showed considerable distortion. Many clear areas containing an œdematous-like fluid or fibrinous exudate existed. In these areas, numerous Gram-negative bacilli were found, and these bacilli also occurred in small numbers all through the gland tissue. Plasma cells (pyronin-methyl-green stain) were very numerous, and in places almost completely replaced the normal lymphocytic tissue. Many of these cells were in a state of division. Large endothelial-like cells were also noticed.

Spleen.—This organ showed evidences of a pre-existent chronic condition. The capsule and trabeculæ were fibrosed and the sinuses greatly dilated. That the organ was involved in the present condition, too, was shown by the congestion of the vessels and the diffuse hæmorrhages into the pulp. Plasma cells were present in the Malpighian bodies and in these latter a Gram-negative bacillus could be demonstrated.

Liver.—The normal lobular formation was discernible and the cells appeared to be well preserved, but were separated to a considerable extent by congestion of the capillary vessels accompanied by an inflammatory infiltration. In the region of Glisson's capsule this infiltration was much more marked, especially around the bile-ducts. Here and there a miliary tubercle was present in the hepatic tissue. Gram-negative bacilli were demonstrated in the spaces between the liver-cells and in the biliary passages. They were present in dense masses.

Kidney.—Owing to the inflammatory infiltration (mainly polymorphic) which was present in this organ, nodular in some places, but in others occurring as diffuse areas, it was difficult to make out the normal structure. Many of the tubules were found to be lying in a bed of polymorph cells. In the lumen of the intact tubules pus-cells were present. The glomeruli were congested and to a certain extent disintegrated. Large numbers of Gram-negative bacilli were found in the abscess areas, some of the tubules containing what may be termed "bacillary casts." The congested glomerular capillaries also contained Gram-negative bacilli.

Urinary Bladder.—The lining epithelium was lacking in many parts, being replaced by a fibrino-purulent exudate containing large numbers of Gram-negative bacilli.

The thoracic organs, beyond showing congestion of the lung capillaries, were not noteworthy.

The case presents several interesting features. It serves to demonstrate that all cases of clinical dysentery in Nigeria need not necessarily be amœbic in type. Especially are those cases to be viewed with suspicion which have blood or pus and

blood in the fæces and in which no *E. histolytica* can be found.

The recovery of the bacilli from the fluid in the gall-bladder leads to a suspicion that this organ may, as in typhoid, harbour the organism for a considerable time (bile carriers). The condition of the kidneys and other organs examined points, without doubt, to a generalized blood infection of a severe nature, with relatively mild local involvement (i.e., of the colon), a condition not commonly met with.

Colon Bacillus Infections (A. Basil Rooke, F.R.C.S., *The Practitioner*, September, 1925).—The author is of the opinion that colon bacillus is extremely prevalent and is the cause of a great deal of chronic ill-health. The stage of invasion is usually ushered in by an acute febrile illness, but it may be insidious in its onset. The condition tends to become chronic. Relapses or reinfections are the rule rather than the exception. The majority of cases are associated with colitis. Gross lesions such as appendicitis, cholecystitis and renal infections are extremely common. Toxic manifestations, such as irregular heart action, mental depression and derangement of thyroid, frequently occur. Treatment: This must be directed towards improving the condition of the intestine, increasing the patient's resistance. In order to prevent the disease from becoming chronic, treatment must continue for a long period after all signs and symptoms have cleared. It is as necessary for the *B. coli* infected patient to have the urine examined from time to time as it is for the syphilitic to have repeated Wassermann tests.

The Vernes Flocculation Test for Syphilis (Adelaide B. Baylis, Adele E. Sheplar, M.D., and Ward J. MacNeal, M.D., *Archives of Dermatology and Syphilology*, August, 1925).—The author is of the opinion that the Vernes flocculation test should be regularly employed in conjunction with the Wassermann test as a help in diagnosis and treatment of syphilis. The result of a single Vernes test is only suggestive unless the reading is high, 0·2 or above. Repeated tests at definite intervals giving essentially the same reading in spite of provocative treatment speak against a diagnosis of syphilis, even though the reading itself be high. On the other hand, a relatively low reading which changes appreciably on repeated tests speaks for a positive diagnosis. Conflicts between the results of the Wassermann and of the Vernes test are especially valuable, as at once a more complete view of all the evidence and the serologic examination of additional specimens are demanded.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

Tropical Medicine and Hygiene

NOVEMBER 2, 1925.

COMPARATIVE ANIMAL AND PLANT PATHOLOGY—EPIDEMIC PLANT DISEASES.

FOR many years the importance of the comparative investigation of diseases of man and the lower animals was completely ignored. Recently, however, the

subject has attracted attention, so much so, that a Section of Comparative Medicine was established three years ago by the Council of the Royal Society of Medicine. This Section is open to both medical men and veterinary surgeons, and the result has been most satisfactory from a scientific and practical point of view.

Though the time for such change is perhaps not yet ripe, it is the belief of the writer of this article that it would be of great scientific advantage to go a step further and include in comparative pathology the diseases of plants. Recent researches have shown that certain flagellates of plants may experimentally cause disease in animals, and it is probable that certain fungi pathogenic to man may live a saprophytic or parasitic life on plants. It is most interesting to see how certain epidemics of plants behave in exactly the same manner as epidemics of man and animals. With regard to this we quote a large portion of an exceedingly interesting article published by F. T. Brooks in *Trans. of British Mycological Society*, p. 299 (August 1924):—

All of us are familiar with disease in an epidemic form as regards illness to which human beings are liable. The widespread occurrence of influenza a few years ago need only be recalled to indicate the chief characters of an epidemic.

At that time many people simultaneously became ill with influenza, which spread with great rapidity from person to person. Thus the principal features of an epidemic are the large numbers of individuals in a population affected by the disease at one and the same time, and the amazing speed with which the malady spreads from the centres where it first occurs.

Plants of economic importance, in which large numbers of individuals of the same kind are usually densely aggregated, are also liable to diseases of an epidemic nature. As in human diseases, plant maladies are frequently caused by parasitic organisms, and epidemic diseases are almost invariably of a parasitic nature.

Not all diseases of plants are of an epidemic nature. Some are sporadic, i.e., occur only here and there and not universally over a wide area. Through neglect, however, a disease which is usually sporadic may assume an epidemic character. Thus silverleaf disease of fruit trees is usually sporadic in a plum plantation upon first appearance, but if neglected so that the causative fungus, *Stereum purpureum*, fructifies upon the dead branches, the disease may become so prevalent as to be an epidemic.

Epidemic diseases are essentially dependent upon two sets of factors for their development, namely, a condition of the host favourable to invasion by the parasite, and an environment of such a kind as to allow of the rapid dissemination of the spores and germination of these upon the surface of the host; these two sets of factors are intimately related to each other, for conditions detrimental to the growth of the host are often favourable to the development of the parasite. As regards the host being in a state of susceptibility to attack, it is a commonplace that individuals, whether of animal or of plant populations, vary greatly in their liability to certain diseases. It is also well known that even the most robust individual may become so weakened as to become susceptible to diseases from which normally he is free. Plants of economic importance, most of which have been in cultivation for long ages, exist in the form of numerous varieties which show marked differences in their susceptibility to disease. Some varieties of wheat are markedly resistant to yellow rust caused by *Puccinia glumarum*, while others are very susceptible; again in potatoes, some forms are badly attacked by the blight fungus and others are scarcely troubled by it. But often even the healthiest forms of cultivated plants may have their vitality so weakened under some conditions as to become a prey to a parasite which usually cannot thrive on it.

Granted, however, that the host plant is in a susceptible condition for attacks, epidemic disease will not follow unless the germs of the parasite are available in abundance and unless environment conditions favour their rapid dissemination and germination upon the tissues of the host. In fact it is not too much to say that weather conditions are usually all important in determining whether the disease appears in an epidemic form or not. This accounts for differences in incidence of such plant diseases in successive years. The prevalence of one of the commonest epidemic diseases, potato blight, is chiefly determined by weather conditions. In a wet summer great damage may be done by the vigorous spread of this fungus, and so rapid is the onslaught of the parasite under suitable weather conditions that potato fields sometimes become black in a day or two. In a moderately dry summer potato blight, though usually present to a slight extent, is of negligible importance. Under these conditions the spores of the fungus are produced in much smaller numbers, and the majority of them, even if they alight on potato leaves, are unable to germinate and cause infection on account of lack of moisture. Correlated with a heavier rainfall, potato blight is generally more severe in the west of England than in the east.

In temperate regions epidemic plant diseases are often checked by the oncoming of winter, during which most of these parasites are not present in an infectious condition. Mildews which are propagated in an epidemic manner during the summer by spores of a delicate nature, usually form another type of spore towards the end of the growing season, which is enclosed in an impervious case that remains sealed until the following spring. At the same time the young stems and leaves, which are the parts chiefly liable to infection by such fungi, either do not exist during the dormant season or have become greatly modified in structure. In the tropics, however, vegetation and weather conditions are both often practically uniform throughout the year, the temperature and rainfall varying but little in successive months. In such a climate there is no close season for fungal parasites and epidemic diseases are greatly to be feared.

The sources of infection of epidemic plant diseases are sometimes mysterious, and much further work is

required in order to elucidate them. Many investigations have been made upon the means of overwintering of *Phytophthora infestans*, and still there is obscurity about it. Recently it has been shown that the mycelium of this fungus possesses a limited power at any rate of saprophytic development in the soil, and it may be that this is one of the ways in which the fungus survives under natural conditions, especially in such warm areas as the Penzance district and the Isle of Wight. It may be that the fungus is really endemic in such centres in a manner somewhat similar to the continued occurence of cholera in certain districts in India in years when the disease is not epidemic.

The balance between host, parasite and environment in the causation of epidemic disease is usually of a delicate nature. A slight change in environmental conditions, which may favour the host or alternatively injure the parasite, may be quite sufficient to prevent the establishment of an epidemic. Thus *P. glumarum* is commonly present in epidemic form on wheat in this country, because the temperatures of the winter are usually insufficiently low to kill the uredospores of this fungus. *P. graminis*, on the other hand, is a comparatively rare fungus here (except on cereals in immediate association with barberry bushes), because its uredospores cannot survive the winter temperatures which are harmless to *P. glumarum*.

There is some evidence, perhaps of a not very critical nature, that the parasite itself may be more virulent at certain times than at others. There is a parallel to this in certain human diseases. For instance, during the last few years there have been successive waves of influenza, some of which were much more virulent than others. This was probably due to variations in virulence of the bacteria causing the disease, although it may be argued that this phenomenon resulted from a special degree of susceptibility on the part of mankind at the time of most serious attack. With plant parasites it is often found that, upon introduction into a new country, they spread with great rapidity during the first few years until a climax of intensity is reached, after which their attack is less serious. Thus potato blight was introduced into Europe during the early part of the nineteenth century and rapidly spread so that in 1840 it was responsible for a complete failure of the potato crop in Ireland, thereby causing a serious famine; it is doubtful whether this fungus has ever been so virulent since. Another illustration may be taken from a disease which has been introduced into this country in recent years. About 1900, American gooseberry mildew became accidentally established in the British Isles, and immediately began to spread rapidly, so that in a few years all fruit areas where gooseberries were grown on a large scale were attacked by the disease. After some years, however, this parasite became less prevalent, and it may be that its period of maximum virulence has passed, although there has been a considerable recrudescence of the disease during 1922 and 1923.

The example of American gooseberry mildew is an illustration of the danger of the introduction of a parasite to a country where it is not native. Sometimes the climatic and other conditions of the new country are unfavourable to the parasite, but frequently it is otherwise, when there is grave risk of the establishment of disease in epidemic form.

Again, when a new plant is introduced into a country, a parasite often attacks it violently, although the pest has only been found hitherto sporadically upon related indigenous plants. Coffee was introduced into Ceylon as a plantation crop about 1870, and an important industry sprung up in connection with it. Soon, however, it began to be attacked by a fungus disease (*Hemileia vastatrix*), which up to that time had only occurred to a slight extent upon jungle plants closely related botanically to coffee. With large numbers of plantations in close proximity to each other, the disease spread rapidly and became so uncontrollable that coffee growing in the island became unprofitable. Heavy losses were incurred, and a few years after the commencement of the epidemic, coffee ceased to be grown on a commercial scale in that part of the tropics. That is an illustration of the danger of disease breaking out in epidemic form upon a newly introduced economic plant, the disease itself, although indigenous, being of negligible importance until the appearance of the specially susceptible plant.

Epidemic diseases of plants are disseminated in various ways. Most of the parasites produce spores which can retain their vitality for considerable periods unless exposed to extremes of temperature, insolation or desiccation. Many of these diseases, therefore, can be distributed over relatively wide areas by means of wind currents. With such a disease as potato blight this is undoubtedly the chief means by which the fungus is spread in an epidemic condition. Upon first development of the fungus in an active or sporing state in any season, the disease in its initial stages is present only on a few plants in the crop. Spores are produced on these plants and are then distributed by wind so that other plants in the vicinity become infected. The same considerations apply to mildews and rust fungi. The power of wind, however, to disseminate fungoid diseases over immense areas has undoubtedly been exaggerated. It used to be thought that disease could be spread in this manner from one country to another over wide tracts of sea, but this has been shown to be untrue. Delicate fungus spores which have been in the air a long time have probably been exposed to many vicissitudes of temperature, insolation and desiccation. These changes greatly impair their vitality and by the time they reach a plant susceptible to infection most of them are dead. It has been demonstrated for instance that bacterial germs are rapidly killed by exposure to strong light, and doubtless the same applies to many fungus spores. Furthermore, spores being light bodies are to a great extent carried by convection currents to the upper atmosphere, where conditions are of a more extreme nature, and from which many of these germs will not fall in a living condition.

Nowadays emphasis is laid upon the need for contact in the dissemination of many parasitic organisms. By maintaining contact is meant, bringing the parasite into the immediate vicinity of a

healthy and susceptible host by means of some living or mechanical agency. This has long been recognized in human diseases, for, in many of these, individuals only become attacked by coming into close association with others already affected, notwithstanding the fact that the germs of many of these diseases must be commonly present in the air. The inability of the germs casually present in the air to cause infection is due partly to the fact that their vitality is rapidly destroyed by exposure to bright sunlight and partly to the germs being present in quantity less than the minimum requisite to cause infection. In connection with the point last mentioned, it is a well-known axiom in medical science that the danger of infection increases with the magnitude of the dose of the disease, so to speak, to which one is exposed; there is no doubt, for instance, that even the healthiest man would succumb to tuberculosis if he inhaled an atmosphere saturated with the tubercle bacillus. With plant diseases the same principles are only just beginning to be recognized. The means by which the germs of these diseases are brought into contact with their hosts are often different from those of animal diseases, but they are none the less sure. It is now known that many infectious plant diseases are chiefly spread by *insect agency*, and occasionally by birds. There is a widespread group of plant diseases of great economic importance, known as mosaic diseases, which are characterized first by a mottling of the leaves with yellow spots and then by general degeneration. No organisms have yet been isolated which can be considered the cause of these diseases, but if the sap of an affected plant is inserted into a healthy one, the latter soon becomes diseased. Such diseases and others of a similar nature are known as viruses. They are of common occurrence in animals and are often supposed to be due to organisms of ultra-microscopic size. Foot-and-mouth disease in animals and the mosaic diseases in tobacco and potatoes are maladies of this nature. Mosaic disease of tobacco is one of the chief factors limiting the growth of the finest kinds of tobacco in those regions of the tropics, such as Sumatra, otherwise favourable for their growth. It has been shown recently that these mosaic diseases are largely spread by means of insects, especially by aphides, which, having visited diseased plants, puncture healthy ones, and thereby insert the virus. Apart from mosaic diseases, insects play an important rôle in the dissemination of plant maladies caused by known parasitic organisms, whether bacteria or fungi. The insect in sucking or biting the tissues of a diseased plant inevitably comes in contact with the germs of the parasite, some of which adhere while it passes to another plant, which may thus become infected. In fact, so intimate is the incidence of certain insect and fungus pests, that widespread opinions prevail amongst cultivators that fungi inevitably follow particular insects. One of the commonest diseases of apple trees is "canker," caused by the fungus *Nectria galligena*, which sometimes follows in the wake of woolly aphis, one of the most serious insect pests of apple trees. This sequence is probably assisted in two ways, first by the insect carrying the spores of the fungus entangled in its woolly appendages, and secondly because the insect punctures the bark, thereby creating wounds by which the fungus can invade the branches. Again, in the rubber plantations of Malaya, one of the diseases of rubber trees is an affection of the bark, which is brought about frequently by the combined action of an insect and a fungus. The insect is a boring beetle which usually attacks only dead wood, but which under certain circumstances invades the bark of living rubber trees, especially if this has been exposed to injury. In the dead wood inhabited by these borers the fungus *Ustulina zonata* is often found growing as a saprophyte, and as the boring insects pass from the dead wood into the living rubber trees they carry with them the fungus which, upon being thus established in the tissues of the rubber trees, spreads rapidly and acts as a destructive parasite. Such instances could be multiplied many times.

Annotations.

Latah in Tripolitania (T. Sarnelli, *Giornale di Medicina Militare*, fasc. II, 1924).—Latah has been described by several authorities on tropical medicine, but the form which is commonly seen in Tripoli resembles that described by Castellani ("Manual of Tropical Medicine," Ed. 1919) as "a mental condition in which suggestion is at once followed by uncontrollable action in the form of echolalia or echokinesia, of which the mind is usually, but not always, conscious." To the usual exciting causes, i.e., auditory, visual, tactile, Sarnelli adds a fourth —emotional. The predisposing cause is racial. The southerners are more frequently attacked, having a very excitable nervous system.

Observations on North China Intestinal Parasites of Man (Ernest Carroll Faust, *American Journal of Tropical Medicine*, July, 1924. Reprint.)—An intensive study of third-class patients on the medical service of the Peking Union Medical College Hospital was undertaken to determine the importance of parasitic infection in clinical diagnoses in North China. Sixty cases were studied. Each case was under careful scrutiny for a period of ten days or more, during which time every stool passed by the patient was examined. In all, 1,409 stools were studied, or an average of 23·48 per patient. Controlled methods of preparation of the stool for examination indicated that concentration methods were valuable only where a single specimen of stool was available for study. In cases where large numbers of stools of the same patient were examined concentration methods added only 10 per cent. to the findings. Forty per cent. of the infections were diagnosed after the first day, 35 per cent. of which were diagnosed first from unconcentrated preparations. Eighty per cent. of the cases studied were found to be harbouring intes-

tinal entozoa. While this infective incidence is comparable to that of a sick population in Central China, it is less intensive than the latter. The respective indices for the two areas are as follows: Central China, protozoa, 228·7; helminths, 234·3; North China, protozoa, 101·6; helminths, 88·03. The clinical significance of the study is demonstrated by the fact that 53·3 per cent. of the series harboured clinically important parasite infections. Twenty per cent. of the cases had a major diagnosis due to parasites; 46·6 per cent. had a minor diagnosis of parasites; 13·3 per cent. of the cases had both major and minor diagnoses occasioned by infections of the digestive tract due to parasites. No proof can be advanced from the study regarding flagellate entozoa in amœbic dysentery that there is a necessary relationship between the two infections. In the cases studied at least 89 per cent. of the patients secured their infections in the North China mesogeographic area. They belong to the lower middle class and the poor class, which groups, on account of under-nourishment, are likely to be more troubled with clinically important infections than are the upper classes. The Chinese, as a people, are not less susceptible to parasitic infection than other peoples, although light infections among Chinese are less likely to be clinically significant than in Occidentals living in China. Improper disposal of night-soil is responsible for all of the helminthic infections in the intestinal tract of man in North China as determined by this study.

The Dysenteries of Cochin China (N. Bernard, J. Bablet and R. Pons, *Arch. des Instituts Pasteur d'Indochine,* April, 1925).—Dysentery holds first place among the endemic diseases of Cochin China, and the number of deaths from it are not few, although they have gradually decreased during the past few years, thanks to the valuable observations carried out by French and other investigators. Since 1918 the Pasteur Institute at Saigon has carefully investigated the subject, and some important results have been obtained. The authors give a very interesting historical account of the disease in Cochin China, and describe the various types found there. The presence of alkalinity, in a pathological stool, contrary to general opinion, is of first importance; it often coincides with the appearance of grave symptoms and disappears with them. Emetin is of great value in the cure of the disease, but its preventive action is almost *nil*.

Malaria in the Kirkuk Division of Northern Mesopotamia during 1923 (William Corner, O.B.E., M.D., *Transactions of the Royal Society of Tropical Medicine and Hygiene*, March and May, 1925).—The main features which have been noticed during 1923 with regard to malaria in the Kirkuk Division of Northern Mesopotamia in dealing with indigenous natives, treatment and preventive measures not being touched upon, are the following: There are two malaria seasons, the main one in summer and a lesser one in the late autumn. The summer malaria season lasted roughly from the beginning of June to the middle of August. It was caused by the malignant tertian and to a less extent by the benign tertian parasite. The autumn malaria season occurred in late October and November, being most marked in the first half of the latter month. It was due to the malignant tertian parasite. Malaria in 1923 showed certain features which were the outcome of malaria in the preceding summer, when it was prevalent in epidemic form. The chief feature was the marked prevalence and predominance of residual quartan malaria, which existed during the first five months of the year until the starting of the malaria season. It is judged that normally quartan malaria is a comparatively common infection, and that fuller explanation of the marked quartan predominance referred to is that it was due to residual infections from an epidemic year occurring in an area where quartan is peculiarly common. Quartan malaria was not confined to any one part of the division, but was equally prevalent everywhere. Malignant tertian was the main cause of the summer and autumn malaria seasons. Infections started somewhat later than the benign form (roughly, fifteen days) and rapidly disappeared with the passing of the malaria season. Crescent infections were comparatively not common. The main clinical manifestation was a quotidian fever of no great severity. Pernicious forms were absent. Benign tertian was the earliest infection to appear in any number with the opening of the malaria season. This parasite seemed to depart markedly from its usual rôle as a cause of relapses, its behaviour as regards disappearance of infection at the end of the malaria season closely resembling that of malignant tertian. There was no evidence that benign tertian was a factor in the autumn malaria season. Quartan malaria—presumably its season of infectivity coincided with the summer malaria season. This, however, could not be proved, fresh cases being obscured by the mass of already existing quartan malaria. Triple infections were comparatively common, especially in the early months. Double infections are common. Quartan malaria, as met with, has quite sustained its reputation as the cause of an extremely chronic infection.

Nomadic Arabs on the whole suffer very little from malaria. Its occurrence can be explained by their habits. During both the summer and autumn malaria season they are in fixed camping grounds, and according to the malarious nature of these grounds so will malaria among them vary. Malaria was most seen in small sections which camped alongside the fringe of villages on the edge of the desert, to the west of Kirkuk and Taza Khurmatu. The Quaraghan-Kifri-Tuz-Tauk-Taza-Kirkuk-Alton Keupri road serves as a rough line of division of malarial endemicity. On the east, or hilly side, malaria is hyperendemic and shows very high spleen-rates. The area to the west, or desert side, shows medium spleen-rates passing to low or *nil* the further

one goes into the desert. Malaria in the Kirkuk division seems to be associated with (*a*) a higher degree of splenic enlargement than that usually recorded; (*b*) very high spleen-rates among the children and often a comparatively high spleen-rate in adults; (*c*) a surprisingly low parasite-rate in children and adults considering the high spleen-rate. The theory is advanced that (*a*) is due to the prevalence of quartan malaria. It is also possible that this fact also contributes to (*b*) and (*c*). Each malaria season was preceded by a marked increase of mosquito-breeding, including *Anopheles*. A feature of the main malaria season was the fact that it lasted throughout the hottest and dryest month of the year, when the 8 a.m. mean temperature was about 90° F. and the mean relative humidity was below 30 per cent. Humidity, within limits, appeared to be a factor of comparatively little importance in influencing malarial prevalence.

Vaccinotherapy in Gangrenous Affections of Fuso-spirillar Association by an Antispirillar Vaccine (R. Pons, *Arch. des Instituts Pasteur d'Indochine*, April, 1925).—The pathogenic action of the spirilla is comparable to that observed in fuso-spirillar affections, in which the spirochæte plays the most important rôle. The germ used as an antigen in vaccination differs from *Spirochæta vincenti* in its dimensions and its cultural properties, but it cannot yet be determined whether or not antigen properties exist which are common to both germs. Antispirillar vaccine has a rapid action on the phagedenism in all cases; four to five injections are enough to put a stop to it. Complete cure of the ulcers is sometimes long, depending largely on the general condition of the patient and on the lesions. The rapidity of the cicatrization of the mucous ulcerations is remarkable.

Raynaud's Disease complicated with Gastric Ulcer (Julius Friedenwald, M.D., and William S. Love, Jr., M.D., *Journal of the American Medical Association*, July 11, 1925).—The case described presents a typical instance of Raynaud's disease complicated with gastric ulcer. While it is most difficult to demonstrate a definite relationship existing between the two affections as occurring in the same patient, it is extremely interesting to note, and it is quite possible to conceive, that both may have originated in a vascular spasm. That similar spastic manifestations of the blood-vessels occur in the internal organs in Raynaud's disease is revealed in the well-observed attacks of hæmoglobinuria and of abdominal colic noted at times in this affection.

Dochez Scarlet Fever Antitoxin in Thirty-one Cases (R. H. Graham, M.D., *Journal of the American Medical Association*, July 11, 1925).—Serum disease occurred in twenty-one cases out of a possible thirty-one. The size of the dose apparently did not influence the reaction. Immunization was established in twenty-four cases, all of those treated the day of exposure. Serum injected the second day after exposure did not protect two patients out of three. Therapeutic injections gave little apparent relief. One advanced case showed no improvement with 40 c.c. of unconcentrated serum, and there was a serious serum disease.

An Epidemiological Study in Leprosy (G. R. Callender, *Philippine Journal of Science*, May, 1925).—A brief study of some of the epidemiological aspects of the histories of 259 lepers has been given in an effort to stimulate the continuance of this method of research in leprosy in the Philippine Islands. Additional evidence is presented that the earliest recognizable lesion is an anæsthetic area. The data on the location of the primary lesion added to the data reported by others favour the theory that the organism enters the body through abrasions or similar wounds in the integument of the exposed parts of the body. The age at which the first symptom appeared in the cases of this series also agrees with the findings of others, that the more susceptible ages are in the first decades, although no age appears exempt, unless we extend the possible incubation period beyond reasonable limits.

Localized Gangrene Following the Hypodermic Administration of Calcium Chlorid (M. G. Seelig, M.D., *Journal of the American Medical Association*, May 9, 1925).—Calcium chlorid administered intravenously in strengths above 1 per cent. is not an innocuous drug. Solutions of 2 per cent. and over show a marked tendency to cause necrosis and gangrene when brought into contact with subcutaneous tissue. When solutions of such strength are used for intravenous administration, necrosis and gangrene constitute a very real menace, because of the danger of some of the solution escaping into perivenous tissues. The poisonous effect of calcium chlorid (marked cardiac depression) may be discounted in a large measure because the dosage commonly used is not large enough to cause toxic symptoms, particularly if the solution is administered slowly. The administration of a 1 per cent. solution (50 c.c. administered slowly) seems to be a very certain protective against all undesirable effects.

Effects of Obscure Lesions on Organ Weights of Apparently Normal Rabbits (Wade H. Brown, M.D., Louise Pearce, M.D., and Chester M. van Allen, M.D., *The Journal of Experimental Medicine*, August 1, 1925).—A group of 350 normal rabbits was studied with reference to the occurrence of obscure lesions of various kinds and the probable or possible effect of such lesions of various kinds or disease processes on organ weights. It was found that so long as the animals remained in apparently good health the values obtained for organ weights of animals with lesions did not differ materially

from those for animals that were entirely free from lesions. There were, however, slight deviations from the normal which appeared to be significant in that they suggested a functional response similar in character to the more marked changes in mass relationships that occur in rabbits presenting clinical symptoms of disease due to the same causes.

Clinical and Serologic Studies of Neurosyphilis with Tryparsamide Therapy (Julian Mast Wolfsohn, M.D., and Carlos Leiva, M.D., *Journal of the American Medical Association*, August 15, 1925).—In a series of thirty-seven cases of neurosyphilis, in all of which antisyphilitic treatment had been given previously, tryparsamide therapy combined with special technique has proved an apparent distinct advance over other forms of treatment. The improvements are most systematic. Tryparsamide in doses of 2·5 grm. may, and does, occasionally cause ocular symptoms, but not more often than do other arsenicals. Tryparsamide is one of the best tolerated of the arsenicals used in the treatment of neurosyphilis. Tryparsamide has little or no effect on the serological reactions in general paralysis. It is distinctly beneficial both clinically and serologically in certain types of tabes. Tryparsamide is a distinct addition to the therapy of neurosyphilis.

Viability of Bacillus Typhosus in Oysters during storage (Fred. O. Tonney, M.D., and John L. White, M.D., *Journal of the American Medical Association*, May 9, 1925).—The longevity of *B. typhosus* in the oyster juice of both shucked and shell oysters in storage varies with the temperature at which they are kept. In general, the temperature best suited for the preservation of the oyster tends to prolong the life of typhoid bacilli in the oysters. Under conditions simulating those of the trade, viz., at icing temperature (45° F.), typhoid bacilli survived for twenty-two days in shucked oysters and for sixty days in shell oysters. No evidence of bactericidal power or eliminative action against *B. typhosus* was observed in living shell oysters during dry storage at 45° F., the microorganisms survive for a longer period than the oysters.

The Reactions of the Miracidia of Schistosoma Japonicum and S. Hæmatobium in the Presence of their Intermediate Hosts (Ernest Carroll Faust, *Journal of Parasitology*, June, 1924).—A comparative study of the reaction of the miracidia of *S. japonicum* and *S. hæmatobium* in the presence of their intermediate hosts has thrown light on the exact relationship obtaining in these respective host-parasite cycles. The free-swimming infective miracidia of *S. japonicum* move about in the top stratum of water. Only those molluscs which pass through this stratum are exposed to infection even if they were otherwise capable of stimulating an attack by the miracidia. The free-swimming infective miracidia of *S. hæmatobium* are equally distributed throughout the water in which they hatch. All snails in the immediate vicinity capable of stimulating an attack by the miracidia are likely to be attacked and infected. Several closely-related species of operculate snails belonging to the genera *Katayama* and *Oncomelania* have been found to harbour *S. japonicum* infection. The active mechanism of the miracidium for the specific molluscan host is probably a chemotactic one, in which the mucous secretion is the substance involved. Although the host-parasite mechanism is based on a precise adjustment, the miracidium is capable of very wide accommodation as regards temperature and H-ion concentration.

A Note on the Viability of Bacillus Dysenteriæ (Hiroshi Kusama, *The Philippine Journal of Science*, May, 1925).—From the experiments on the viability of *Bacillus dysenteriæ* in artificial and natural dysenteric stools the following conclusions are drawn: Unlike the vibrio of cholera, *B. dysenteriæ* is fairly resistant to drying. It will survive longer in a sterile than in a normal fresh stool. *B. dysenteriæ* will survive a considerable length of time in water. In salt solution, and consequently in sea water, it will survive longer than in tap or distilled water. Physiological salt solution and bile are favourable media for the survival of *B. dysenteriæ* in the stool and the combination of the two may help to preserve *B. dysenteriæ* in the stools of dysentery patients and carriers, in at least a certain percentage of cases.

Some Clinical and Laboratory Aspects of Amœbiasis with a Preliminary Report on Yatren Treatment (John F. Kessel, Ph.D., and Otto Willner, M.D.).—The actual practical significance of the presence of *Endamœba dysenteriæ* in the stool is not altogether determined, although the old conception of the pathology produced by this organism is certainly far too narrow. To promote further study the laboratory diagnosis has to be put on a sound basis by creating a specially equipped protozoological laboratory in charge of an efficiently trained microscopist. The clinical observations should be made from a more uniform point of view and be guided by a detailed outline of study. With *E. dysenteriæ* present in the stools specific treatment should be given to (*a*) anyone showing symptoms possibly relating to amœbiasis, or (*b*) any healthy carrier who has a reasonable chance of not being reinfected. The toxic effects of emetine render its use indiscriminately in all cases undesirable. Of nineteen cases positive for *E. dysenteriæ*, which were treated with yatren, seventeen (92 per cent.) were negative to these organisms in follow-up examinations made from three to six months after treatment. These results indicate that yatren is a satisfactory therapeutic agent in the treatment of chronic amœbiasis. Preliminary treatment of acute

manifestations of amœbiasis with yatren indicates that it may even replace emetine-bismuth-iodide in amœbic dysentery.

Pathogenicity of Trichomonas Intestinalis (Hiromu Tsuchiya, M.D., *Archives of Internal Medicine*, August 15, 1925).—*Trichomonas hominis* is not a pathogenic but a harmless flagellate present in the large intestine. Whether they are present in large or small number, neither laboratory nor clinical pictures bear evidence conclusive enough to warrant pathologic diagnosis. Diarrhœa, mentioned by many as characteristic of trichomoniasis, has no clinical aspect in the series described in this paper; instead constipation is a common occurrence with diarrhœal history in the past. Furthermore, proctoscopic diagnosis emphasizes the fact that constipation is a usual accompaniment in these cases. Nervous systems and nutritional disturbances as manifested by these cases are attributed not to the presence of *Trichomonas hominis*, but to some organic or functional disorder or to constipation secondary to such. The intestinal flora is independent of the presence of *Trichomonas hominis*. The type of intestinal flora does not alter the number of the flagellates. Hegner's assumption in regard to albino rats is not feasible in its clinical application.

Abstract.

AN OUTLINE OF THE HISTORY OF PLAGUE IN HONG KONG.[1]

By A. G. Millott Severn, M.D., B.A., D.P.H.
Assistant Medical Officer of Health, Hong Kong.

The revival of plague is one of the most important and striking facts in epidemiology. In May, 1894, the world was alarmed by its severe outbreak in Hong Kong, in which year probably more than 5,000 persons died here of this disease, amongst a far smaller population than we have at the present day.

In the early days of the epidemic in this colony, the ætiology of plague being unknown, little was done in the way of quarantine. Hong Kong's unrivalled position as the centre of shipping in the Far East enabled plague to spread along maritime trade routes in the course of three or four years to a vast number of ports in many countries throughout he world, including Japan, the Philippines, the Pacific Islands, South America, Madagascar and Mauritius. Land-borne plague travels slowly, but it is rapidly disseminated by marine traffic.

India became infected, almost undoubtedly from Hong Kong, in 1896; the first cases occurring in Bombay. The Indian Empire offered a fertile soil, and plague caused the loss of more than ten million lives in the subsequent twenty years.

The plague apparently came to Hong Kong from the Province of Yun-nan, about nine hundred miles distant, where it was known for many years to be endemic. Interesting confirmation of the antiquity of plague in this part of China is contained in the information given me by a Chinese medical man, himself a native of this province. He says that a time-honoured curse, one of the worst in the wide range of Yun-nanese maledictions, is to call upon the gods to afflict one's enemy with Yang-tzu, the name by which the plague is known in the local dialect. In 1893, plague, known as Luen-tzu, was present in Pak-hoi; later it made its appearance in Canton, where it prevailed in the form of a severe outbreak. The first cases are known to have occurred several months before the commencement of the Hong Kong epidemic, and an enormous number of deaths, probably not less than one hundred thousand, were attributed to plague in that year, before the epidemic subsided.

There must have been a good deal of confusion as to the true nature of this disease at that time. Bubonic plague was present in Macao, an early Portuguese settlement on the estuary of the Canton River, in 1895. It is curious to note that it was undiagnosed as such, and was known as "foul-gas fever."

The Sanitary Board of Hong Kong was instituted in 1883, its activities being chiefly directed towards the scavenging of the city and the improvement of housing conditions. On the outbreak of plague in 1894, the board was enlarged and its scope extended to include anti-plague measures. The Sanitary Board has retained these functions, with little modification, to the present day. It is worthy of note that there was no law to enforce the notification of deaths at this time, and a medical officer of health was not appointed until the year 1895.

In spite of the existence of a Sanitary Board, it was generally conceded that the housing conditions and general sanitation of the city of Victoria at this time were deplorably bad, and that the colony was inviting pestilence.

The outbreak of plague threw a tremendous strain upon the small Government medical staff available, and members of the Army, Navy and police force were enrolled to cope with the various aspects of the epidemic. It is gratifying to read of the splendid conduct of these medical and lay volunteers, English and Chinese, who, almost without exception, showed the utmost courage under difficult and trying circumstances.

A silver medal was struck in their honour, similar to the usual war medal, and presented to all those who went through the 1894 campaign.

The united efforts of this improvised staff were directed almost entirely to treatment, and the provision of temporary hospitals on land and in the harbour; in addition to the inspection and disinfection of infected premises, together with other anti-plague measures as were evolved from time to time.

Meanwhile, the attention of the scientific world

[1] Abstracted from the *Journal of The Royal Sanitary Institute*, July, 1925.

became focused on Hong Kong, and research work was commenced, notably by Japanese medical men, who were quickly on the scene. The efforts of the Japanese bacteriologist, Professor Kitasato, were early rewarded by the discovery of the *Bacillus pestis* on June 14, 1894, at the Kennedy Town Barracks Hospital, Hong Kong.

The Government medical officers regretted that they were too busy looking after the sick to devote much time to research, and consequently the honour of the discovery of the plague organism fell to a visitor.

Bubonic plague has always been by far the most common type in South China. Primary pneumonic plague, together with its different mode of transmission was early recognized in Hong Kong. Considerable public sympathy was aroused by the death of the nursing sisters of the Government Civil Hospital in the year 1898, from pneumonic plague. Twenty years ago the coincidence of primary pneumonic plague was stated to be as high as 4 or 5 per cent. of the total cases, doubtless many of these were secondary pneumonic plague; it is certain that authentic cases of the primary pneumonic type have been of rare occurrence during recent years. This may be considered remarkable in view of the ill-ventilated houses and overcrowding which prevail.

A good deal of research was done in the colony by medical men of several nationalities, who were given every encouragement by the Government. Many of their methods and deductions have, however, been subjected to criticism.

A number of interesting and voluminous special reports on various aspects of plague were published here at intervals between the years 1895 and 1915. A list of these publications which I have consulted is given at the end of this paper.

The term "bubonic fever" was employed in several of the special reports, mainly on the ground of its supposed resemblance to typhus.

A peculiar Chinese document of "precious instruction to rescue the world" was circulated in 1894, purporting to be written by Kwan Tai, the God of War, through the medium of a "planchette." This curious publication gives, amongst other "revelations," a liturgy to be recited by those who would escape the disease, and prescribes some elaborate native medicines for its cure.

As previously stated, the plague bacillus was discovered in Hong Kong, and a mass of evidence collected and tabulated, but the majority of the early investigators seem to have been obsessed with the idea that bubonic plague was primarily a gastro-intestinal infection. They were never able to discard this view, and it was left to the Indian Plague Commissions to determine the rôle of the rat and the rat-flea in the ætiology of bubonic plague.

In the first plague report, issued here in 1895, Dr. Lowson, then in charge of the epidemic hospital, says: "The question of the infection of rats previous to the epidemic being noticed in human beings has been made too much of."

Dr. Hunter, the Government bacteriologist, also criticized and discredited the conclusions of Simond, published in 1898, that rat-fleas conveyed the infection from rat to man. These and similar statements were indeed unfortunate, though it is proverbially easy to be "wise after the event."

Research was conducted here in 1894 to determine whether the beaten-earth floors of infected houses contained the *B. pestis*. This kind of ground-surface was then very common in the poorer Chinese houses where the bulk of the cases occurred, and was usually soaked with excrement and filth. However, as far as plague was concerned, the results were negative.

A curious belief in the immunity of opium smokers was prevalent at this time, so much so that people crowded into the opium divans for refuge; living and sleeping therein. This was shown to be a false notion, and probably spread by those interested in the opium trade. Statistics showed that opium smokers and eaters were no more immune than the rest of the community. The authorities, however, put much more faith in tobacco as a prophylactic, and all the plague staff were allowed to smoke freely.

Contaminated water was blamed for a long while; this led to the closure of a large number of domestic wells, which were then very common in the city of Victoria. Even the water of the harbour was under suspicion, and was examined for *B. pestis*.

The view of infection via the alimentary tract, due to specifically contaminated food, was widely accepted for several years, though there were those who considered "emanations from the breath and skin" as being the most important ætiological factor.

Large numbers of animal-feeding experiments with plague material were undertaken, and colour was lent to the gastro-intestinal hypothesis, as many of the animals and birds died of septicæmic disease resembling plague. However, the results were inconclusive, and were eventually disputed in Hong Kong in 1904 by the present medical officer of health, who expressed his entire disagreement with this view.

It was reported at one time that the *B. pestis* was found in low grades of Chinese rice. In connection with this view of the specific contamination of food, it was thought that possibly the plague bacillus might exist outside the body, in symbiotic union with certain of the vegetable moulds.

The sanitary state of Hong Kong in the plague year was wretchedly bad, particularly in the central districts of Victoria. The habits and surroundings of the Chinese were admittedly filthy in the extreme. Back-to-back houses were common, and these houses were of a very bad type, built like tunnels, often dilapidated and obstructed with cubicles and cocklofts, i.e., intermediate floors. The houses were damp, overcrowded, and almost entirely deprived of ventilation and light. Latrine accommodation was inadequate and drainage was bad or absent.

The first efforts at plague prevention were directed towards improving this state of affairs. The sani-

tary board acquired wide powers of dealing with insanitary areas, and at a later date attempted to improve the type of Chinese house, and compelled the provision of open space at the rear of buildings.

About ten acres of the most densely populated part of the city was resumed by the Government at the height of the epidemic. All the inhabitants were evicted and housed elsewhere. The streets were walled up and guards were stationed to prevent ingress.

Plague was made compulsorily notifiable, but this law was widely evaded. Inspection and registration of common lodging houses and coolie houses was enforced.

It was considered that the public latrines were possibly one of the most potent factors in the spread of the disease and chlorinated lime was freely used in these buildings.

House-to-house visitation was instituted to discover those dead or infected with plague; obvious cases were removed to the improvised hospitals or to the " Hygeia," a hospital hulk which was moored in the harbour near West Point. Suspects were sent to the Tung Wah, a large Chinese hospital, for observation.

Contacts in these infected houses were provided with clean clothes, their own clothing was removed, together with bedding and similar material, and sent to the steam disinfecting station, the clothing being tied up in sheets dipped in a solution of Jeyes' fluid and conveyed through the streets in closed baskets.

There were mat-shed shelters available for those whose houses were undergoing disinfection; the contacts were not detained, but were allowed to go about their business.

Houses in which cases had occurred were disinfected by spraying the walls with a solution of perchloride of mercury, one in a thousand; or by fumigation with free chlorine, generated by mixing common salt, manganese dioxide and dilute sulphuric acid in requisite proportions, producing a continuous liberation of the gas for some hours. Floors and furniture were scrubbed with a solution of Jeyes' fluid, 5 per cent., and the walls were then limewashed, chlorinated lime being added in the proportion of one pound to the gallon of limewash.

Extraordinary precautions were taken in the disposal of the dead; special plague cemeteries situated at a considerable distance were allocated for their burial, and it was a rule that the graves should be covered with six inches of cement mortar or similar material.

Inoculation with what is described as " Haffkine's prophylactic fluid " was introduced in 1902, and in that year 587 persons, mostly employees of the Board, were inoculated. Inoculation was made a condition of employment in the case of disinfecting coolies, rat-catchers and case-removing coolies. As far as was known, plague did not occur in any of these persons, though the vaccine frequently produced a violent reaction and some disability. In spite of generally favourable reports, the public took little or no advantage of preventive inoculation.

Yersin's serum was brought here at an earlier date. In 1896 Dr. Yersin came to Hong Kong with a supply of serum for the treatment of plague, but there were no suitable cases in the hospitals at that time, and he went on to Amoy to carry out his tests.

Various modifications in prophylaxis were adopted from time to time, as a result of experience. Many of the early methods were expensive and comparatively futile in the light of later knowledge.

The fumigation of houses with chlorine gas, produced by the action of dilute acid on chlorinated lime, was tried on a large scale. The difficulty of effective fumigation of Chinese houses by this means was, however, recognized, as was also the possibility of vermin escaping destruction in the joints and crevices of the woodwork and furniture.

A recommendation was later made to the Government to introduce a portable Clayton gas apparatus, which could be conveyed on a lorry to houses requiring disinfection, but the hilly nature of the city and district rendered this suggestion impracticable.

The systematic disinfection of the town was attempted, but proved a very costly undertaking and was abandoned in favour of a scheme of " general house-cleaning," in which a staff of European sanitary inspectors and coolies was constantly employed.

Districts were treated in rotation, so that each tenement house was cleansed at least three times a year. This important measure is still being carried out with great success and with but slight modification. It has all the advantages of simplicity, efficacy and economy.

Each inspector is allotted a certain number of floors daily; the occupants turn out their household possessions, the floors and cubicles are washed out, and the bed-boards are cleansed in portable iron tanks.

An inspection is made for minor structural illegalities, rat-runs and similar holes are filled in with cement at once and all rubbish is carted away.

When first instituted soft soap and hot water were used, later a solution of carbolic acid, and now an insecticidal mixture, 1 per cent. kerosene emulsion, is employed.

Defects in premises, or breaches of regulations or by-laws, are recorded for the service of legal notices on owner or tenant for their remedy.

As soon as the importance of rats in the ætiology of plague became appreciated comprehensive measures were put into force for the abolition of hollow walls, ceiling and stair linings. Concrete ground surfaces and efficient iron gratings guarding openings into houses were required; lath and plaster walls were instituted, and attention was paid to proper drainage.

Rats were caught in large numbers, and subjected to routine macroscopic and microscopic examination. It had been a matter of observation for a long while that the mortality from plague amongst the rat-catchers was exceptionally high.

A reward of two cents, later increased to five

cents, per rat was given, but this had to be stopped when it was found that the Chinese were importing rats from Canton for the sake of the bonus.

The laying down of a rat virus (Danysz's), for the purpose of spreading fatal disease amongst rats, was advised, but the results were disappointing, and did not justify its general use.

Wholesale rat trapping and poisoning was not a great success, and met with a good deal of passive resistance on the part of the Chinese. The rat-traps distributed in the Chinese houses were usually found, on inspection, to have the springs of the traps released. The net result was that few rats were caught by this means.

Another unsatisfactory aspect was that the rat-catching coolies were often known to threaten to report plague-infected rats as coming from a certain house if "squeeze" were not paid them. Householders were often willing to pay this form of blackmail rather than submit to the inconvenience of disinfection, the up-rooting of floor-boards, removal of ceilings, and similar measures, which were enforced by the authorities in the case of premises in which infected rats were reported to have been found.

On the whole, it was considered a better policy to reduce the accessibility of rats to dwellings, workshops and warehouses; and, as far as possible, make such premises unattractive to them.

Apparently no special protective measures, such as have been employed in India, for food and grain stores and godowns, were devised or enforced locally.

General rat poisoning takes place throughout the colony twice a year, by means of pellets of barium carbonate and molasses; about 350,000 of these pellets, together with instructions in English and Chinese, are distributed to householders on each occasion.

Rat-boards coated with a mucilaginous mixture are also supplied on demand by the sanitary department.

The present system of "rat-bins" has encouraged the destruction of rats, and has eliminated some of the disadvantages which have been mentioned. Small iron bins containing kerosene emulsion are bolted on to lamp-posts and other prominent places, and an inscription in Chinese characters requests the public to deposit any dead rats therein. These bins are emptied twice daily; the rats, which are labelled with the number of the bin in which they are found, are sent to the mortuary for examination by the Government bacteriologist. All rats are examined macroscopically for signs of plague infection, and blood-smears and smears from the splenic pulp of 10 per cent. of the rats are examined microscopically for the *B. pestis* at the Bacteriological Institute.

The *Mus rattus* and *M. decumanus* are both common in the colony; they occur roughly in the proportion of two of the former to three of the latter; both are liable to infection.

Seven to eight hundred of these rat-bins are in use throughout Victoria and Kowloon.

Two or three thousand rats, probably only a small proportion of the rat population, are collected weekly in this manner, and examined for evidence of plague.

An infected animal cannot always be traced to the actual house wherein it died, but a valuable indication is obtained as to the district in which plague may be expected to occur. Houses in the close vicinity are subjected to individual inspection, the cleansing gangs may be diverted to the suspected district and other suitable preventive measures speedily put into force.

Certain of the local anti-plague measures, with slight modifications, have been employed in the Philippine Islands for some years with marked success.

Though there is still a great deal to be done before Hong Kong may be regarded as a health resort, nevertheless, the result of the effort during the past thirty years of the medical and sanitary departments in the case of this one disease is very striking. Other natural causes, well known in epidemiology, have doubtless contributed to this end, yet Canton, South China and the Straits Settlements had many cases of plague last year. It is noteworthy that amongst our closely-herded population, approaching a million, the incidence of plague has been gradually reduced, until at the present day we can claim that there has been no notification of either rat or human plague in the Colony of Hong Kong from September, 1923, until the present date.

Current Literature.

THE INDIAN MEDICAL JOURNAL
August, 1925.

A Preliminary Note on the Pharmacology and Therapeutics of Adhatoda vasica (Basak) (R. N. Chopra and S. Ghosh).—The chemical analysis of *Adhatoda vasica*, a small evergreen subherbaceous bush which grows all over the plains of India and in the lower Himalayan ranges, shows the presence of two active principles: (*a*) an alkaloid vasicine whose empirical formula is $C_{11}H_{12}N_{20}$=molecular weight. (*b*) Traces of a volatile principle of the nature of an essential oil. Vasicine has no marked action on the alimentary canal or on the circulation. It produces slight but persistent bronchodilatation in experimental animals and this effect is considerably increased after the administration of atropine. Clinically a fluid extract prepared from the leaves has well-marked expectorant properties and relieves bronchial spasm. It has no effect whatever in pulmonary tuberculosis.

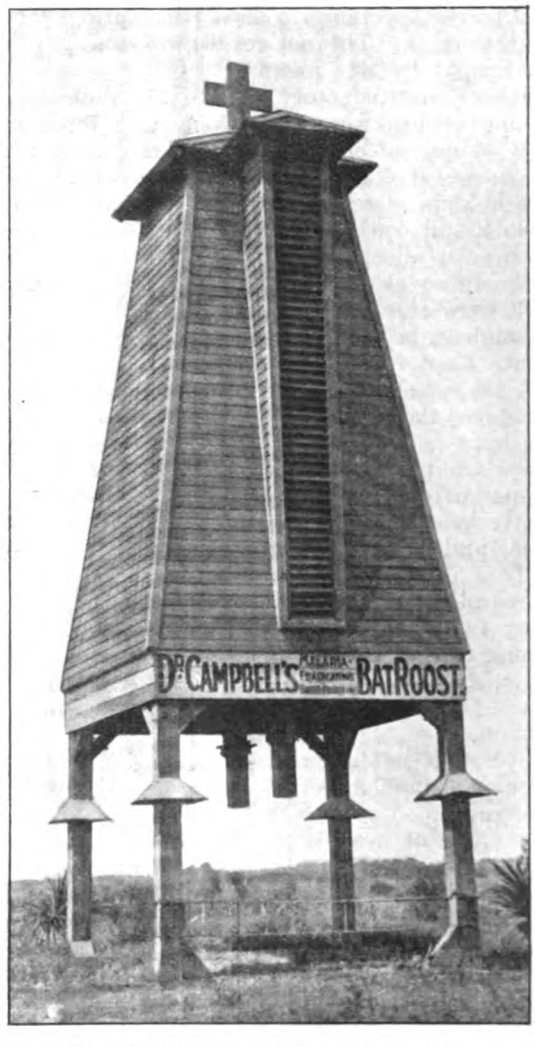
Mercurochrome 220 *in the Treatment of Malaria* (A. Neave Kingsbury and K. Kanagarayer).—A case of benign tertian malaria is reported in which 0·3 grm. of mercurochrome was given over three days. On the withdrawal of aspirin and three days after the last mercurochrome injection a typical

rigor occurred with a temperature of 102·9° F. The malignant tertian case received a similar quantity of mercurochrome and fever recurred two days after the last injection. The dye appeared to have little effect on the number of malaria parasites in the peripheral blood and caused no modification in their standing properties. In neither case did albuminuria develop. It is considered that the action of mercurochrome on malaria parasites is practically negligible, and that, in view of the unpleasant sequelæ which result from its exhibition, it should not be given in cases of malaria fevers.

Excision of the Pineal Body of a Monkey under Intra-arterial Anæsthesia (J. P. Arland).—In this case the anæsthesia was very sound. The common carotid artery was clamped to shut off the blood current, in order to provide a bloodless field for the action of the anæsthetic. The presence of blood has a retarding influence on the power of the anæsthetic solution. The addition of gum acacia combined with adrenalin increases the duration of the anæsthesia. The internal jugular vein was clamped in order to lock in the injected solution as far as possible. No signs of shock were noticed either during or after the injection. The monkey recovered.

Cataract Extraction. Notes on 17,000 Operations (J. M. Macphail).—The author gives an account of his thirty-four years of work in the Mission Hospital, one of the three maintained by the Santal Scottish Mission, in Bamdah, a village in the Province of Bihar. Although the number of operations for cataract is high, the disease is not common in Bamdah; most of the cases are patients who have travelled long distances to be treated at the hospital, which is situated on a popular pilgrimage route. The chief cause for cataract appears to be the glare of the sun.

Treatment of Hæmorrhoids by Strangulation and Snipping Method (D. R. Kehar).—The author has treated about five hundred cases of hæmorrhoids, external and internal, during the last five years by the "strangulation and snipping method," and finds that the results are efficacious and long lasting. The patients treated were from 14 to 50 years of age and the hæmorrhoids were in all stages of inflammation. The patient can be discharged on the seventh or eighth day after operation. This method has also been found useful in cases of partial prolapse with piles.



Correspondence.

To the Editor of the JOURNAL OF TROPICAL MEDICINE AND HYGIENE.

SIR,—I have recently returned from one of my trips to Texas, during which I was shown what appeared to me to be a rather original scheme for the extermination of mosquitoes in the neighbourhood of a large lake south of the city of San Antonio, where the insects bred in large numbers, causing a great deal of trouble for many years.

A few years ago, at the suggestion of Dr. Campbell, a local doctor, bat towers were erected, since when the insects have been practically exterminated. The towers, which are about 40 ft. high, are erected near the lake, and once the bats are introduced no further attention is called for.

The originator of these towers, Dr. Campbell, claims a certain royalty on each tower constructed,

Bat Roost, Mitchell Lake, San Antonio, Texas.

though I am not aware to which countries this would apply.

The cost of erection is about $2,500 each, including Dr. Campbell's royalty. In the present case the bats were in existence on the spot in small numbers, but they were made to congregate by a special bait which is only known to the originator and his family.

I am, Sir,
Yours faithfully,
(Signed) L. MAURICE COCKERELL,
M.I.M.M., &c.

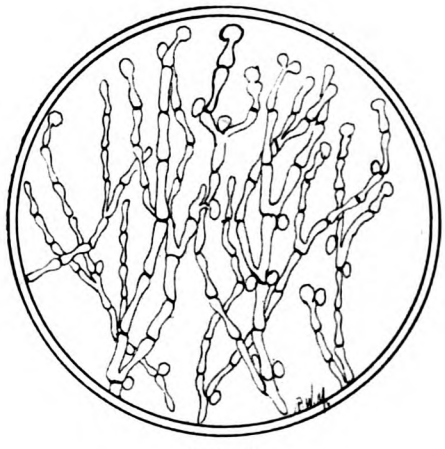
SOME INTERESTING DISEASES OBSERVED IN THE CLINIC OF THE BANGKOK CENTRAL HOSPITAL.

By RALPH W. MENDELSON, M.D., D.P.H.

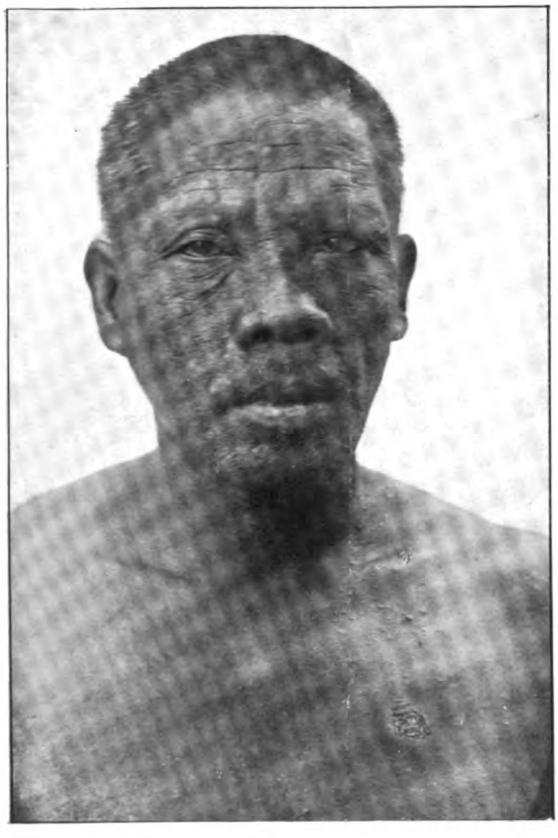
(Principal Medical Officer of Health, Royal Siamese Government, Bangkok, Siam.)

SIAM offers a rich field for research in medicine, both tropical and cosmopolitan, but so far it has hardly been touched. The varied duties of the medical officer of health do not permit a serious effort in this interesting line of work, but advantage is taken to observe the patients presenting themselves for treatment in the Clinic of the Central Hospital. Here are to be seen between 19,000 and 20,000 cases every year. These patients come from every part of Siam and represent every grade in society. If one had the time I think it would be possible to fairly accurately describe every disease to be found in the country from observations in this clinic alone. For fear this statement may discourage the reader from continuing this paper I will at once state that such an ambitious programme is entirely foreign to the object of this article. It occurred to me that it might be of interest to report some of the more interesting cases that lend themselves to photographic study, and with the idea of making the report as attractive as possible the legend has been limited to a short description of each illustration. Interesting febrile and other conditions are necessarily omitted.

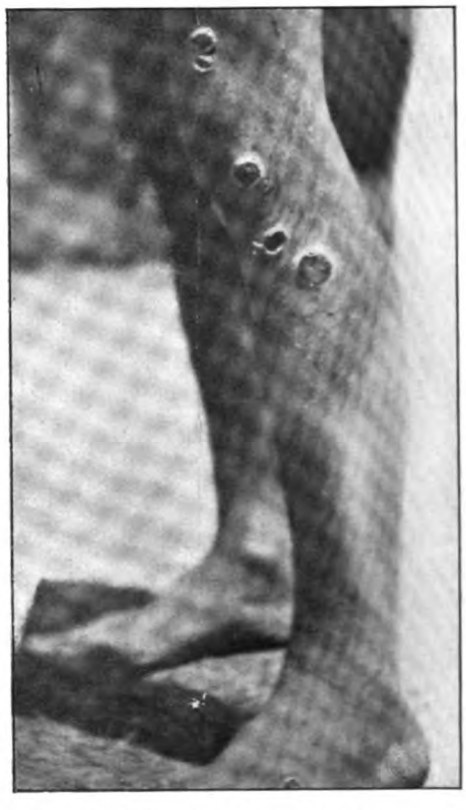
The frequency of dermatomycosis is the same in Siam as in other tropical countries. A great variety of unidentified fungi have been observed in these cases; an example is here shown.



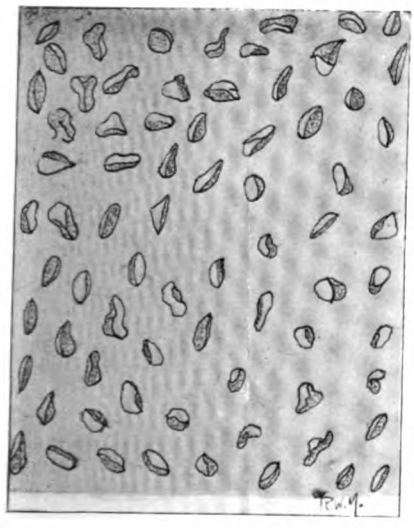
CASE 1.



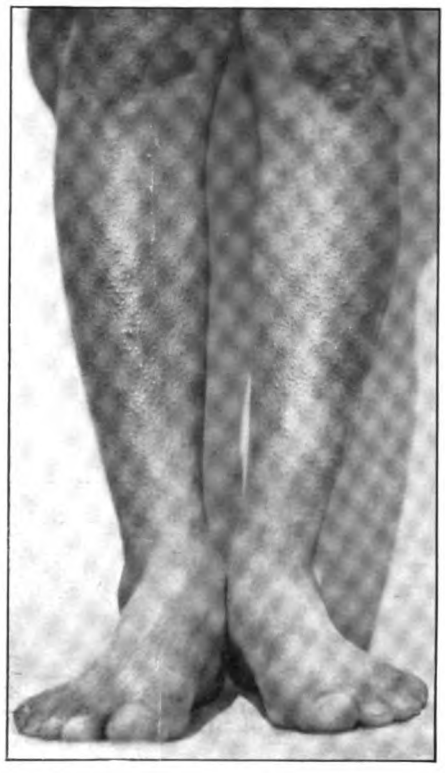
CASE 1



CASE 2.



CASE 3.

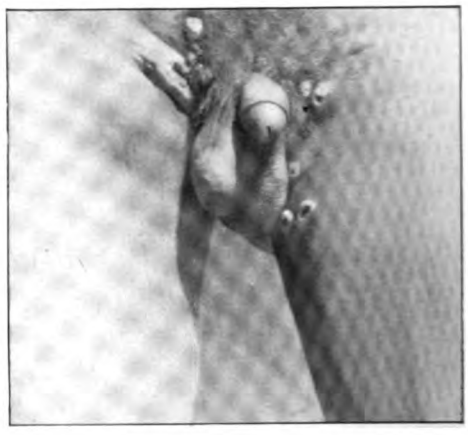


CASE 2.—Pityriasis nigra, caused by a fungus of the genus *Cladosporium—C. mansoni* Castellani 1905. A few cases have been observed.

CASE 3.—Acladiosis. This is an interesting dermatomycosis caused by a fungus isolated by Castellani in Ceylon. I have observed only one case in the clinic. It is caused by *Acladium castellani* Pinoy. Potassium iodid acts well, local treatment is unsatisfactory.

CASE 4.

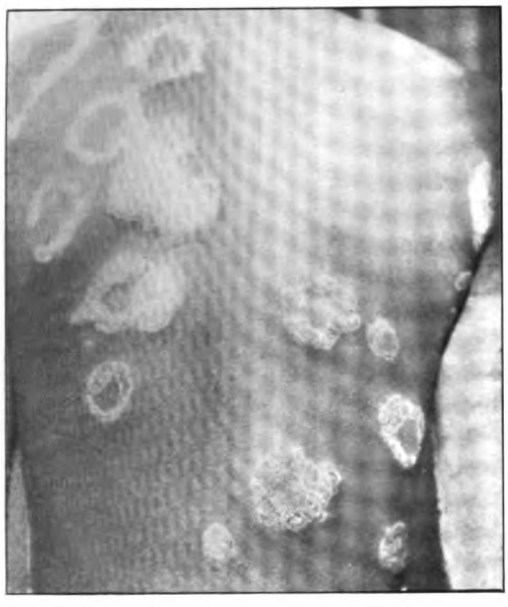
CASE 5.—Keratosis pilaris, an inflammatory condition that is characterized by an accumulation of horny material in the follicular orifices. It produces a nutmeg-grater-like appearance. It is very chronic and does not respond readily to treatment.



CASE 4.—Tinea labialis (betel-nut dermatitis of the lips). Due to an as yet unidentified mould that can be demonstrated in the betel-nut cud and the lesion. I have observed many of these cases. The condition has not been reported from other countries. May be caused by a variety of fungi.

CASE 6.—Tuberculosis verrucosa cutis. A few cases have been seen. The lesions begin as small papules, and increasing in number coalesce to form verrucose patches. Infection as a rule occurs from without.

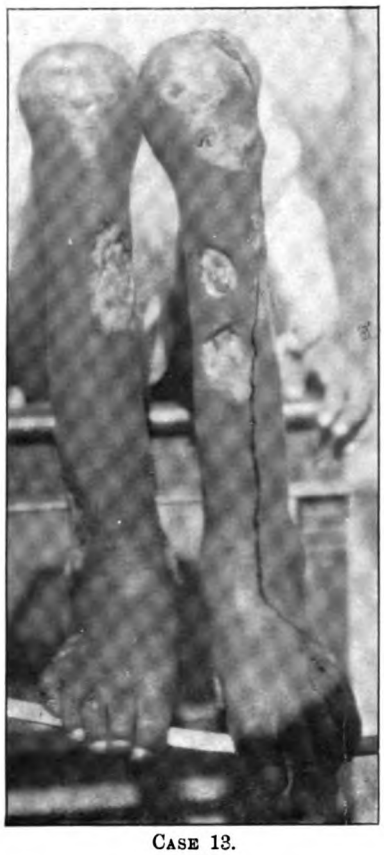
CASE 7.—Xanthoma tropicum (juxta-articular nodules). A very common condition in Siam. Sections usually present the appearance of a hard fibroma, although various degenerative changes have been observed, fatty, amyloid, &c.



CASE 8.—A disease (dermatitis cupoliformis) first described by Castellani as occurring in Europeans resident in Ceylon and due to a streptococcus belonging to the erysipelatous group, called *Streptococcus tropicalis* Castellani, 1914. I have observed a few cases in native Siamese.

CASE 7.

CASE 9.—Vitiligo, a common condition in Asiatics. This particular photograph is that of an Indian patient in the insane asylum. The condition itself is probably a trophoneurosis.



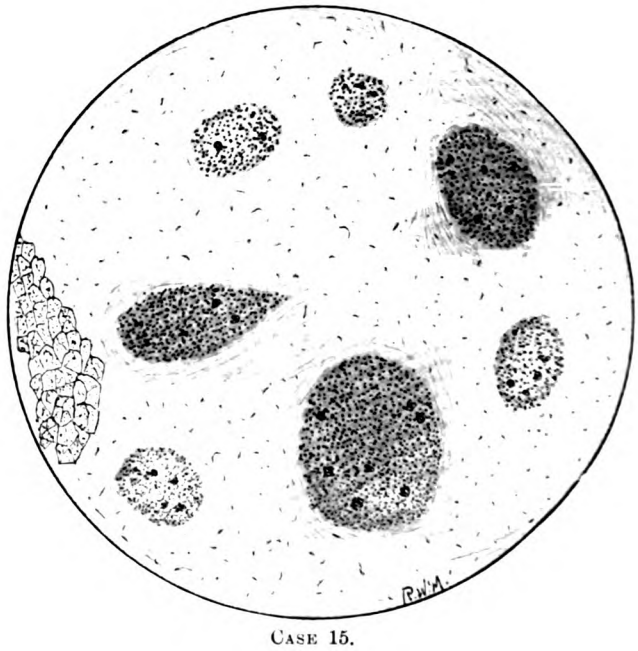
CASE 10.—Leprosy is very common in this country. I present this case as a very fine example of an acute exacerbation of an old chronic condition. This patient has suffered from leprosy for many years. He has never had any treatment except native. Three days before coming to the clinic he developed this very acute eruption on the various nodular lesions present.

CASE 11.—Elephantiasis, not common in Siam. This is a case of elephantiasis of the labium in which microfilaria could at all times be demonstrated in the peripheral circulation.

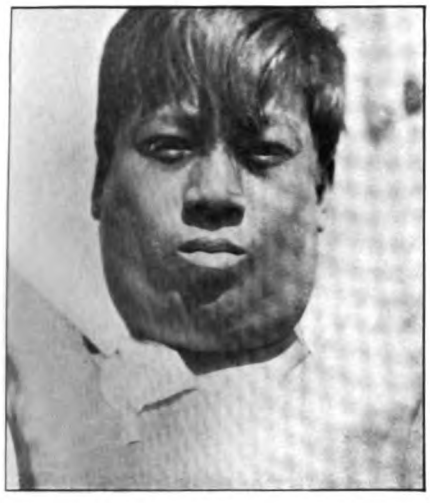
CASE 12.—Hyperpituitarism and hypopituitarism. These two patients came to the clinic within three days of each other, both from the interior of Siam. Patient on the left is 19 years old, 7 ft. 3 in. in height. Family history negative. Patient on right is 21 years old and 3 ft. 5 in. in height. Both exhibit the usual symptoms, and X-ray pictures confirm the diagnosis. One shows a very enlarged, the other a small pituitary fossa.

CASE 13.

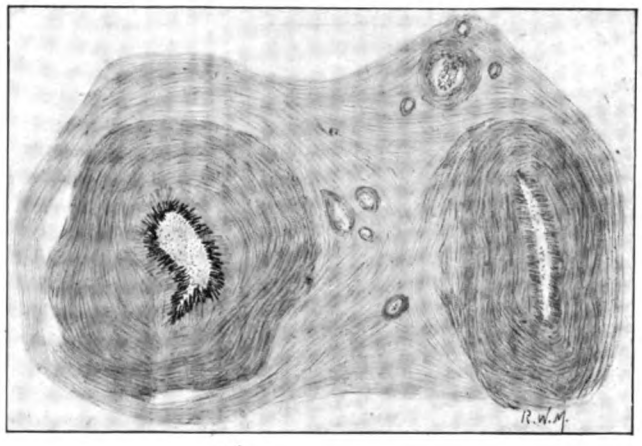
CASE 13.



CASE 13.

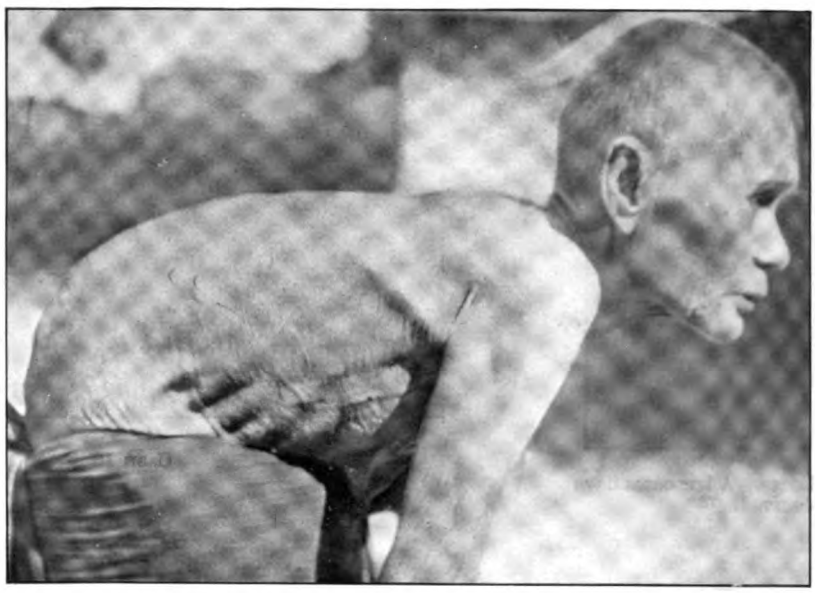


CASE 13.—Frambœsia tropica. A very common disease in Siam. Intensive treatment throughout the Kingdom will soon be taken up by the Department of Public Health. The photographs show the type of disease that is not uncommon. Have seen many cases that could be diagnosed as gangosa.

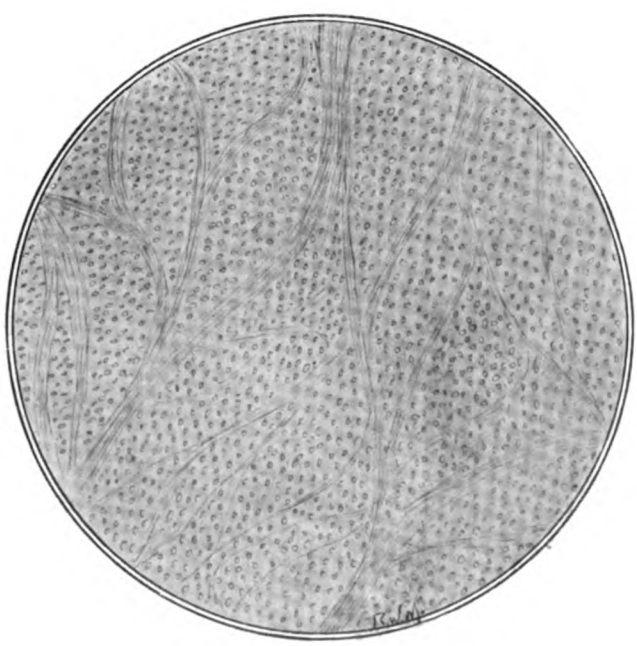


CASE 14.—Just to show the type of case that one sees in the clinic. Cysts of the ovary are common, but patients refuse operation until almost incapacitated.

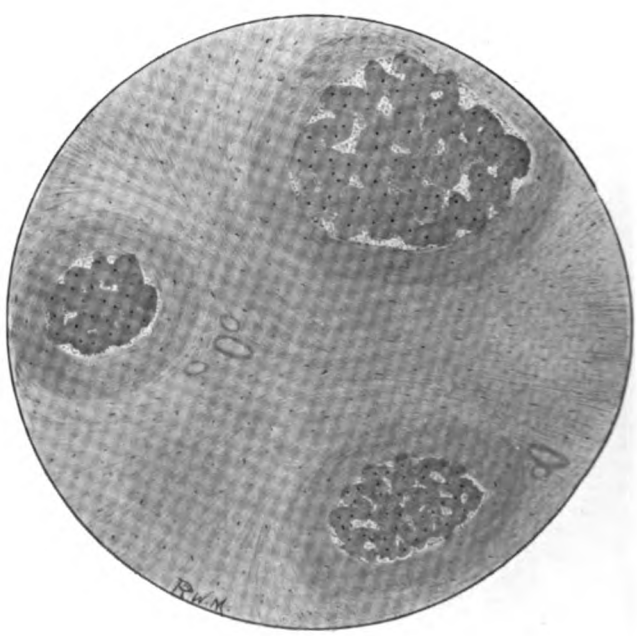
CASE 15.



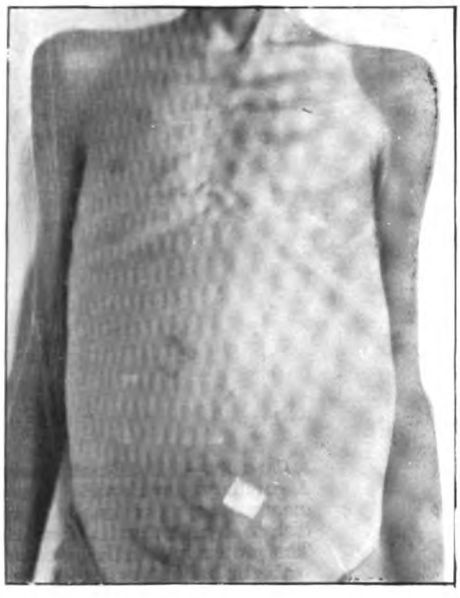
CASE 15.—Hodgkin's disease. A few cases have been observed.



CASE 16.



CASE 16.—Arteriosclerotic gangrene in a male Chinese aged 21 years. Patient died in hospital one week after being admitted. The section is from the tibial vessels. Notice the great increase in the muscular coats.

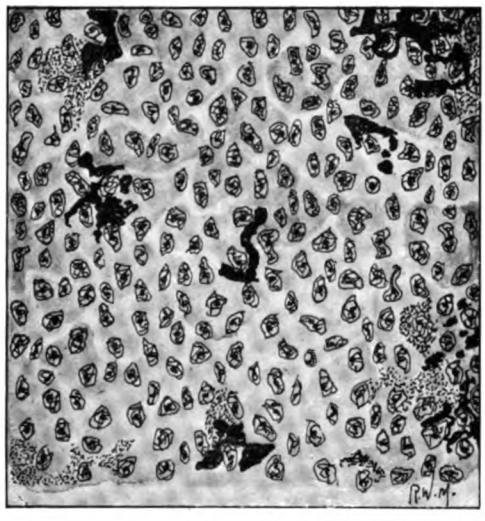


CASE 17.—Acquired kyphosis. The Siamese have a habit of resting on their haunches, especially the lower-class Siamese. This extreme type has often been seen.

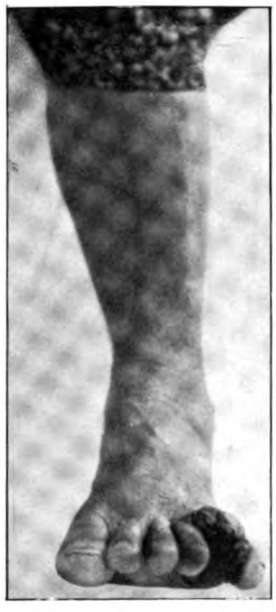
CASE 18.

CASE 18.

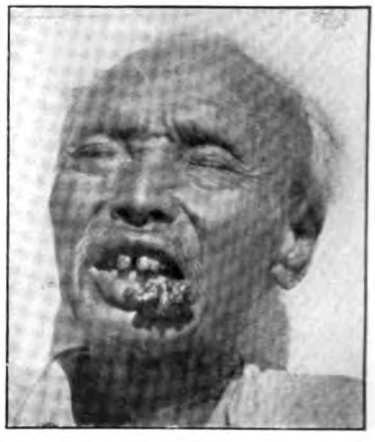
CASE 18.—Tropical febrile splenomegaly. Cases observed both in Siamese and Chinese. Spleen puncture negative, although one genuine case of kala-azar has been seen. Patient claimed never to have been outside of Siam. Died in the hospital, and smears from the spleen were positive. This particular case is negative as far as bacteriological findings are concerned. The spleen and liver showed a high degree of fibrosis, characteristic of all of the cases that came to post-mortem examination.



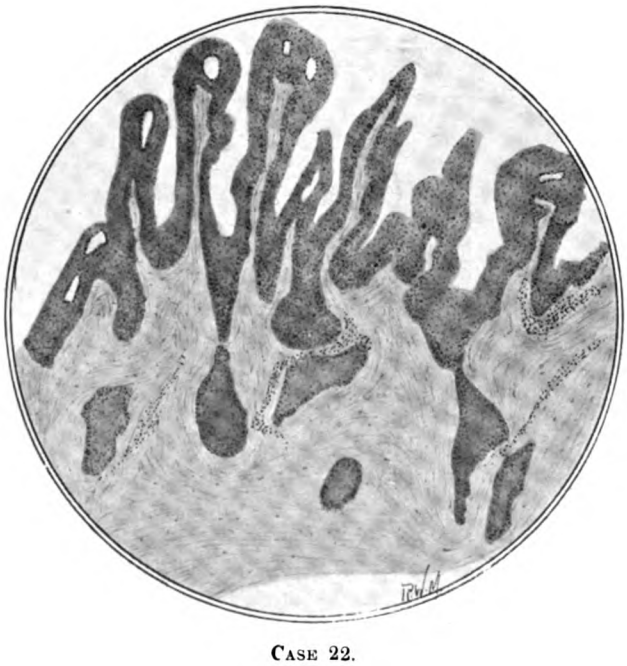
CASE 20.

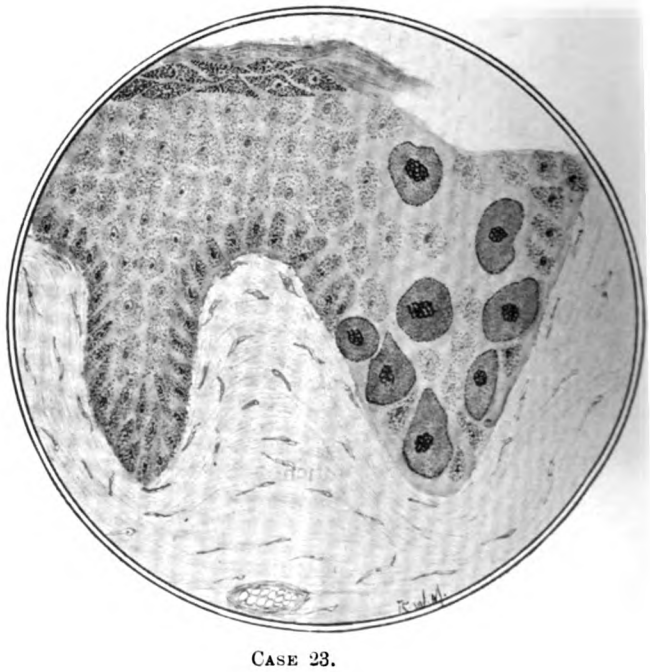


CASE 19.—Congenital bilateral ptosis. Have recently noted two cases. One in a female and one in a male. Treatment was refused as being too severe.



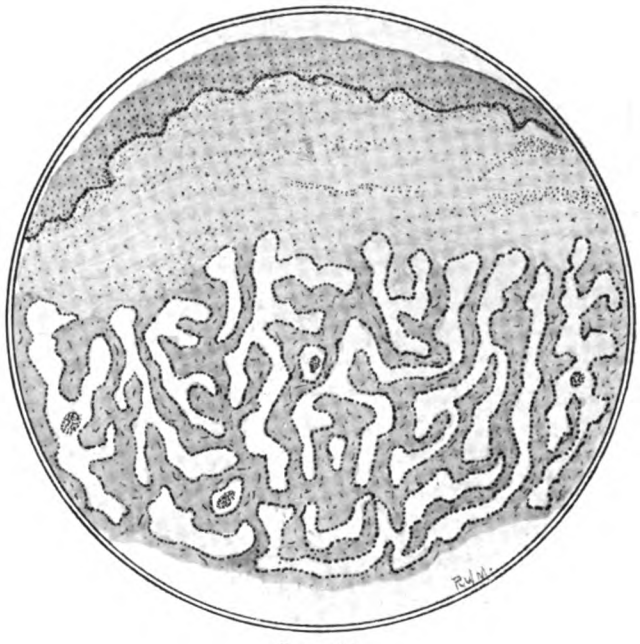
CASE 20.—Spindle-cell sarcoma of the jaw. This illustrates to what an extent a malignant growth may progress before the patient will seek relief.





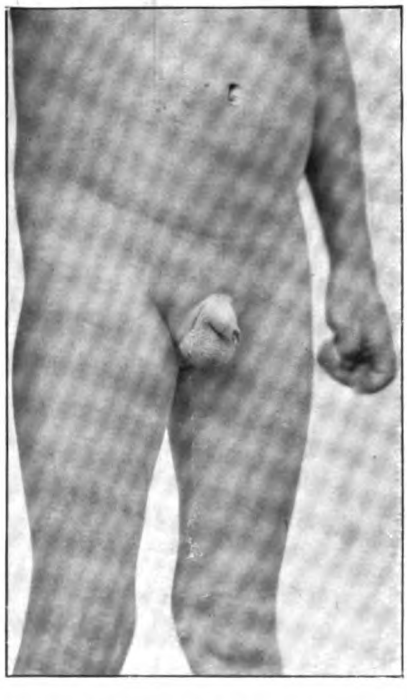
CASE 21.—Melanotic sarcoma of the foot. This patient also refused treatment. This growth, according to the history obtained, is of only three weeks' standing.

CASE 22.—"Betel-nut carcinoma." A papillary growth with late carcinomatous degeneration is a common disease in patients who chew betel-nut. The protruding teeth in combination with the irritant action of the mouth secretions must certainly have a determining action upon the delicate epithelium of the mouth and lips.



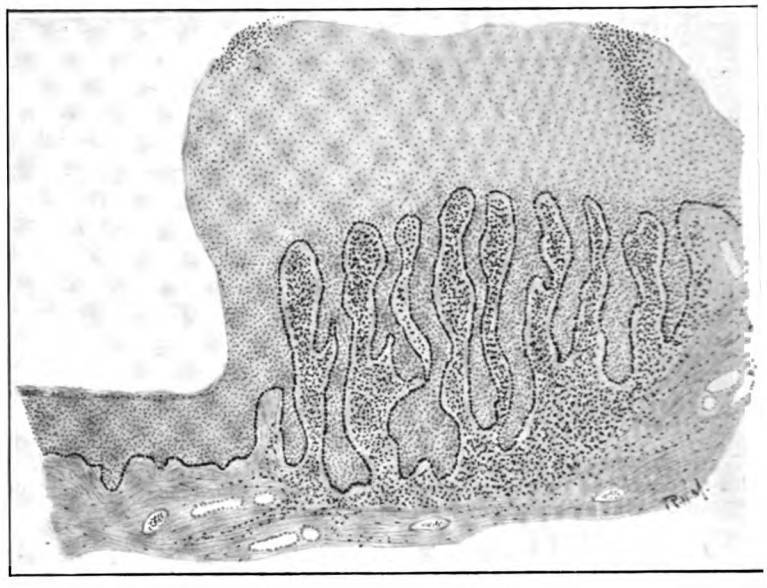
CASE 22.

CASE 23.



CASE 23.—Paget's disease of the nipple. This patient refused treatment after a section had been obtained for diagnosis. This is the only case I have seen here.

CASE 24.



CASE 24.—Multiple papillary adenomata of the sweat glands. This is a rare condition. This type of growth is very apt to become malignant on account of the large amount of epithelium found lining the spaces in the tumour mass. The patient is a Siamese, male, aged 47. These tumours first appeared about seven years ago as very small subcutaneous growths. The one on the back had ulcerated and was removed with several of the others. They are extremely vascular and in excising them one must be sure to go a considerable distance beyond the growth in order to prevent copious bleeding.

CASE 25.—Climatic bubo. Not uncommon. This photograph is that of a Siamese boy, aged 16. The history and examination were quite negative. The boy had been ill some few days, slight fever and some pain. The swelling gradually cleared up under symptomatic treatment.

CASE 26.

CASE 26.—Granuloma inguinal. A few cases are observed every year. Whe permitted we excise the growth, as local treatment is unsatisfactory, patien becoming discouraged and refusing to return as requested.

CASE 27.

CASE 27.—Ulcus tropicum. Very many cases are seen in this clinic. We have had good results with protargol ointment, have treated some cases with salvarsan, but have not noted the immediate results reported by other physicians.

No. 28 is an example of phallic worship. This lad is wearing these wooden penises to safeguard himself against evil spirits and incidentally to give him "strength."

No. 29 is that of a superstition regarding the ætiology of mumps. This lad has painted on his cheek the image of a tiger within a circle. He is under the impression that the disease is in some way caused by rats and therefore by painting over the swollen gland a picture of a member of the cat family the evil spirits of the rats will leave him and he will recover.

No. 30.—This travelling dentist came to see us one day to inquire whether or not some of our patients needed the services of an expert. His credentials are in the form of strings of teeth extracted from unfortunate victims.

No. 31.—The young man in the picture is having his ears "manicured" in a local barber's shop. This is a common practice here and is the cause of considerable ear trouble.

SCHISTOSOMUM ? SPINDALIS MONTGOMERY IN A ZULULAND SCHOOLBOY.

By F. G. Cawston, M.D.Cantab.

In 1906 R. E. Montgomery [1] described a new schistosome from the mesenteric vessels of *Bos indicus* at Muktesar, India, which, in view of the spindle-shaped appearance of its ova, he named *Schistosomum spindalis*.

This schistosome was also reported from Sumatra [2] in the same year. In 1918 Lieut.-Col. Glen Liston and M. B. Soparkar [3] published a report of the life-cycle of this parasite, showing that *Planorbis exustus* served as the intermediate host in Bombay. They readily obtained the adult parasites from a goat; but failed to secure any from a monkey which was made to drink water swarming with cercariæ.

In the Annual Report of the South African Institute for Medical Research [4] for 1922, *S. spindalis* is reported as occurring in the urine of a patient from the Johannesburg General Hospital.

Ova resembling those of *S. bovis* Sonsino have been found in the urine of several patients at the Natal coast and in the Belgian Congo; but, until February, 1925, no ova resembling those of *S. spindalis* had been detected.

On February 9, 1925, a schoolboy of 14 came to me for treatment, complaining of four months' hæmaturia since bathing in the Umhlatuzi River in Zululand. There were no other symptoms. The urine contained numerous ova of *S. hæmatobium* and about a fifth the number of spindle-shaped ova, possessing a straight border when viewed from the lateral position, but presenting the appearance of the outline of those of *S. bovis* when viewed from above. The terminal spine was not heart-shaped as that of *S. bovis*. The fully developed ovum measured 0·24 mm. in length; but, as the extremities of the shell were solid, the miracidium did not appear to be much larger than that of *S. hæmatobium*.

The usual degenerative changes were observed in both varieties of ova whilst the patient was under intravenous antimony. No local or general toxic effects were noted throughout the series of injections, from a quarter to one and a half grains of the potassium salt being given to this schoolboy daily or on alternate days, until the urine was free from ova on the twenty-seventh day. In all he received a total of 17 gr., compressed 4 gr. tartar emetic tablets containing 2 gr. of sodium chloride being dissolved in 8 c.c. of boiling tap water just before the injection. No ova could be found in rectal washes or in the fæces, either by centrifugalizing or by the use of a saturated solution of salt.

Dr. W. F. Rhodes reported an eosinophilia of 11 per cent. during the first week of treatment. This might partly be due to the presence of *Ankylostoma duodenale*, which was the only pathological condition detected from examination of the fæces, and was treated with ol. chenopodium. He drew attention to the fact that the spindle-shaped ova showed much greater degenerative changes than did those of *S. hæmatobium* during the first week of the antimony treatment; this suggested that infection with *S. spindalis* would respond rapidly to antimony therapy.

Some Recent Aspects of the Epidemiology of Clonorchis Infection in China (Ernest Carroll Faust, *China Medical Journal*, April, 1925).—Experimental study by Kobayashi and morphological study by Chen Pang of an extensive series of specimens from man and reservoir hosts of *Clonorchis* have demonstrated that a single species, *Clonorchis sinensis* (Cobbold), is present throughout the Far East. This parasite is present in a relatively large percentage of the coolie class as well as in the better classes of the native population in South China, but it is fairly uncommon in the indigenous population in the Central Provinces and is unknown as a parasite of man in North China. On the other hand dogs and cats are lightly infected in South China. In Central China they have an infection of 75 to 100 per cent. In North China the infection in the mammalian reservoir hosts ranges from 25 to 37 per cent. These varying incidences of infection are accounted for by the following facts:—

(1) Uncooked or insufficiently cooked fish is eaten by man only in South China.

(2) The fishes of Central and North China harbouring the encysted larva have the greater part of the infection on the underside of the scales and seldom in the flesh. In South China the limited examinations made justify the belief that the infection is mostly confined to the flesh.

(3) Although the only snail infected in Japan, Korea and Formosa is described as *Bythinia striatula* var. *japonica*, the parent form in China, *B. striatula*, collected from Soochow, Anking, Paotingfu and Peking has not yet been found naturally infected. On the other hand, *Melania hongkongensis*, collected near Shaohsing, has been found to harbour the fluke.

(4) Various fishes, both top- and bottom-feeders, have been found to harbour cysts of a fluke, proved experimentally to be *Clonorchis sinensis*. These cysts are resistant to drying, salting and putrefaction of the medium, but are killed in a short time by soaking in Chinese wine or vinegar.

GORGAS AND YELLOW FEVER.[1]

THE charming biography of Dr. Gorgas, which has recently been published by Marie D. Gorgas and Burton J. Hendrick, and should be read by everyone interested in tropical medicine, shows how, in the words of his biographers, "at every stage of his career William Crawford Gorgas seemed to confront the gaunt spectre of yellow fever." Nevertheless, Gorgas's first attempt to get to grips with yellow fever ended in failure. It was in 1877, while still a medical student at Bellevue, that the great yellow fever epidemic, which is still a horrifying memory to the older generation, started in Memphis. In company with half a dozen students he left for the plague-ridden city to offer his medical services. The authorities, however, met this group of pilgrims on the outskirts of the town, thanked them for their generosity, but refused to grant them admission.

In 1882, soon after he had qualified and joined the medical department of the United States Army, he was sent by the chief surgeon of the department as the most progressive young surgeon under his command to deal with a yellow fever epidemic which was then raging at Brownsville, on the Rio Grande, although at that time he himself had never had yellow fever, nor had he even seen a single case. During this epidemic Gorgas was himself stricken with yellow fever, and had a severe attack. Fortunately for mankind he recovered, and thus became immune to the disease for the remainder of his life. From now onward the Government summoned him wherever yellow fever appeared, and he was twice sent to Barrancas, in Florida, to deal with outbreaks of the disease, and so successful was his management of these epidemics that he gained much reputation in Army circles.

In 1898 Gorgas was appointed chief sanitary officer to Havana, the home of endemic yellow fever. The city, which now came under the jurisdiction of Gorgas, was little better than a huge cesspool. At this time yellow fever was looked upon as a "filth disease," and so Gorgas, who had been sent to Havana to eradicate this disease, placed his chief reliance in general sanitation. As Gorgas surveyed the rotting city its most pressing need was only too apparent. "Let me only give it a good scouring and a good bath," he said to himself, "and yellow fever and other diseases will disappear." He set to work with an energy and a completeness that soon brought unique fame to his name. Almost magical results were achieved, so that in a few months Havana had been transformed into a city which was said to be as orderly, as clean, and as civilized in appearance as Fifth Avenue itself. As the result of these measures the general death-rate of the city immediately declined; such diseases as typhoid and dysentery all but disappeared. As regards yellow fever, however, the disease at which they were chiefly aiming, they produced not the slightest effect. Here, then, was proof enough of the incorrectness of the prevailing theory that yellow fever was a "filth disease," and some other hypothesis must be found. The transmission of disease by insects was now beginning to attract attention. Indeed, as long ago as 1881 Dr. Carlos Finley, a physician practising in Havana, had proclaimed that yellow fever was transmitted by the *Stegomyia* mosquito, but had never been able to substantiate his thesis. Even before this Sir Patrick Manson, in 1880, had discovered the transmission of filariasis by mosquitoes, and in 1887 Theobald Smith and Kilborne had proved that Texas fever in cattle was transmitted by a tick, whilst in 1897 Sir Ronald Ross had demonstrated that the infecting agent in malaria was the *Anopheles* mosquito. Then came Dr. R. H. Carter's

[1] "William Crawford Gorgas—His Life and Work." By Marie D. Gorgas and Burton J. Hendrick. Lea and Fibiger, Philadelphia and New York. Price 5 dollars.

observations on the spread of yellow fever with the time relationship between exposure to infection and contracting the disease, which suggested an "extrinsic incubation." The paper embodying these vitally important observations of Dr. Carter was refused by a medical journal as too long. Reed, however, who was conversant with Manson's and Ross's work on mosquitoes, gave them most painstaking study. "Are you sure your dates are accurate," he asked Carter, who replied that he had no doubt on that point. "Then," said Reed, "it spells an insect host." With these ideas in his mind Reed joined the Yellow Fever Commission of 1900 and 1901, his fellow commissioners being Lazeau, Carrol and Agramonte. Guided by the genius of Reed this commission definitely solved the problem and proved beyond any shadow of doubt the part played by the *Stegomyia* mosquito in the transmission of yellow fever. Unfortunately, this work cost Lazeau his life and Carrol a severe attack of the disease. Gorgas was quick to grasp the significance of these results. "If it is the mosquito," said Gorgas, when the Reed experiments were on the way, "I am going to get rid of the mosquito." And get rid of them he did, notwithstanding that mosquitoes abounded in countless billions and Havana and its environs were so full of them that they filled every alleyway, every street, every house, and every nook and cranny of the city, and even at times settled over the community like a cloud. The fact that the *Stegomyia* was a house mosquito, however, enormously helped the anti-mosquito campaign. Gorgas began his anti-mosquito campaign in March, 1901, and the results were startling. For 140 years prior to this, Havana had not been free from yellow fever for a single day, whereas subsequently only five cases occurred, and these in the July and August of the same year. It is true that there was another outbreak in 1905, but this was promptly checked by the application of Gorgas's methods. Since then eighteen years have passed without a single case having occurred. He next turned his attention to the Panama Canal zone, where epidemics of insect-borne diseases—yellow fever and malaria—had defeated de Lesseps and the French in their attempt to build the canal. Gorgas introduced his methods into the canal zone and instituted a vigorous anti-mosquito campaign on the same lines as that which had been so successful in Havana, although he had to fight much official interference and obstruction in doing so. Yellow fever was banished from Panama and the building of the canal was brought to a successful issue.

Since then the methods of Gorgas have been followed wherever yellow fever existed, notably in New Orleans and in Rio de Janeiro and other parts of tropical America, with such success that yellow fever has almost entirely been abolished from the surface of the globe. Honours fell thick and fast on to Gorgas for the part he had played in the eradication of yellow fever, not the least important being the presentation of the Insignia of a Knight Commander of the Most Distinguished Order of St. Michael and St. George, by King George in person, as Gorgas lay dying in the Queen Alexandra Military Hospital, London, whilst on a visit to England in 1920.

"Hail, Router of the Plague of flies! Hail, Isthmian Conqueror true!
Gorgas, to that wise Goddess dear, the Gorgon death who slew!"

S. E. T.

Annotations.

Sugar-content of the Blood in Runners following a Marathon Race, with Special Reference to the Prevention of Hypoglycemia (Burgess Gordon, M.D., L. A. Kohn, M.D., S. A. Levine, M.D., Marcel Matton, M.D., W. de M. Scriver, M.D., and W. B. Whiting, M.D., *Journal of the American Medical Association*, August 15, 1925).—Marathon runners who completed the race of 1924 and showed blood-sugar levels below normal mere placed on a moderately high carbohydrate diet during this year's training season. In addition, they were advised to take a large amount of carbohydrate twenty-four hours before the race. Another group of runners who developed symptoms of weakness and hunger in the 1924 race were studied during this year's training season with the purpose of determining, if possible, at what stage in a 25-mile run the symptoms of hunger and weakness were likely to develop. It was found that this was apt to occur between the fourteenth and eighteenth miles. Therefore, in addition to being advised to eat moderately large amounts of carbohydrates before the race, these athletes were supplied with glucose candies to be eaten from time to time while running. In addition, they were supplied with tea containing a large amount of sugar at stations along the course. The blood-studies showed normal sugar levels in all runners, in contrast to the low figures obtained last year. There was also a striking improvement in their general physical condition. In a number of instances the running time was faster than that in the year previous and the participants finished in better condition. It seems, therefore, that the picture of exhaustion, weakness, shock and other symptoms of hypoglycemia following prolonged effort may be prevented by the adequate and timely ingestion of carbohydrate.

Plague Fleas, with Special Reference to the Milroy Lectures, 1924 (L. Fabian Hirst, M.D., D.P.H., *Journal of Hygiene*, July, 1925).—The geographical distribution of the different species of rat-flea is one of the most important factors governing the spread of plague. *Xenopsylla cheopis* is the most effective transmitter of both epidemic and epizootic bubonic plague in all parts of the world. The relative immunity of certain parts of India and Ceylon from plague is to be primarily

attributed to the prevalence of an inefficient plague-carrying flea on the rats of these localities, viz., *X. astia*. Climatic conditions play only a secondary part in limiting the spread of the disease in these relatively plague-free localities. Plague infection can be maintained in such localities by the importation of *cheopis*-infected merchandise. Climate does not exert an equal effect upon the transmitting power of different species of flea. Numerous attempts to transmit plague from rat to rat by means of *X. astia* at room temperature during the plague season at Colombo have all failed. *X. astia*, however, can carry plague from rat to rat under climatic conditions favourable to plague transmission. Continuous transmission of plague from rat to rat has been obtained with *X. cheopis* in Colombo under exceptionally unfavourable climatic conditions. Both plague and *X. cheopis* have a very irregular distribution within limits of Colombo City. The co-efficient of correlation between two periods of human plague incidence and percentage of *cheopis* to total rat-fleas of all species in fourteen districts of the city is 0·95, probable error 0·02, for both periods. There is a close relation between premises infested with *X. cheopis* and premises where plague-infected rats are found. A threefold relationship exists between the amount of imported grain, the prevalence of *cheopis* on rats, and the incidence of plague in the localities where grain is stored in Colombo. The measures so far devised for combating plague among Oriental populations, tolerant of all forms of animal life, have not proved conspicuously successful. Due recognition of the importance of the flea species factor should lead to marked improvement in plague preventive measures in many parts of the world. A rat-flea survey of all the principal plague areas, especially the ports, becomes urgently necessary. The exports from localities where *X. cheopis* is found to be prevalent upon the rats should be considered actively dangerous when the locality is plague-infected, and potentially dangerous even if it is plague-free, since the continual importation of *cheopis* into a locality where this flea is not indigenous may eventually result in the extension of plague infection to a new area. It is agreed that the export of produce, especially grain, from plague-infected ports should be controlled by international agreement. The limitation of imported *cheopis* and plague to definite zones in such localities as Colombo greatly facilitates the task of plague prevention, since all available resources can be concentrated simultaneously, or successively, on the infected areas. In such instances it is possible to mark out the potentially plague-infected zones by the simple and accurate method of surveying the rat-fleas.

Specificity of the Sero-reaction in Experimental Syphilis with Special Reference to the "Sachs-Georgi" Reaction (Satoshi Takenaka, *Acta Dermatologica*, January, 1925).—Comparative experiments with human serum indicate that although the Sachs-Georgi reaction and the Wassermann reaction are not in absolute agreement in all cases, they are in accord with each other in the great majority of cases (93·2 per cent.). When they disagree the Sachs-Georgi reaction is oftener in agreement with the clinical features. In the cases of rabbit syphilis, it was shown as the result of comparative studies made systematically that the two reactions, although they disagree in parts similar to the cases of the human sera, are of similar type as regards the entire course of the appearance, continuation and disappearance of the positive reaction, and, therefore, there are no fundamental differences between them, except that the Sachs-Georgi reaction is considered to some extent more sensitive than the Wassermann reaction. The results with human sera and those of the systematic comparative studies of experimental syphilis indicate that, if circumstances permit, it is better to employ the two reactions simultaneously, but in cases where the execution of the Wassermann test is not practical it is considered fully justifiable to substitute the Sachs-Georgi reaction for the Wassermann reaction. Care must be used, however, since the choice of the antigen is more important in the Sachs-Georgi reaction than in the Wassermann reaction, to employ only an antigen prepared and certified at some fully equipped laboratory.

A Comparative Study of Clonorchis Sinensis (Cobbold) (Dr. Ch'en Pang, *Transactions of the Fifth Congress of the Far Eastern Association of Tropical Medicine*).—*C. sinensis* is the common parasite of man and domestic mammals, especially the cat and dog. It is found less frequently in the liver of the marten, the wild cat, the badger, and perhaps other host species not yet investigated. The size of *C. sinensis* is relatively variable even in one host. On the other hand, the eggs have a uniformly constant size. Although there are different sizes of worms, there are no indications of specific differences in the internal anatomy of the specimens examined. The liver distome which the author examined belonged to one species, *C. sinensis* (Cobbold).

Radiotherapy in the Treatment of Tuberculous Cervical Adenitis (Morris K. Smith, M.D., and J. Gardner Hopkins, M.D., *Journal of the American Medical Association*, July 25, 1925).—The object of the study of the cases described in this paper was to estimate the value of Roentgen-ray therapy with excision in the treatment of tuberculous adenitis. Surgical experience, as expressed in such reports as that of Dowd, has shown that in early cases with a localized mass of involved nodes excision gives a high percentage of cures. In such cases, permanent cure by the Roentgen-ray is frequently possible, but seems less certain. The possibility that large firm nodes will break down under Roentgen-ray treatment must be considered. In choosing the method of treatment for such an individual case, the uncertainty and tediousness of radiotherapy must be weighed against the operative risk

and resultant scar after surgical procedure. There are, however, other cases in which complete excision is impractical or impossible, many of which can be definitely cured by the Roentgen-ray. It is not always a question of choice between surgery and radiotherapy, as incision and aspiration are surgical procedures indispensable to success in many cases in which the Roentgen-ray is used. The author is convinced that both surgery and Roentgen-ray therapy have important places in the treatment of tuberculous adenitis.

Treatment with Intraperitoneal Injection of Neo-arsphenamin (Heyworth N. Sanford, M.D., *Journal of the American Medical Association*, July 25, 1925).—From the results of experiments on animals and the clinical data obtained from ten cases, it is judged that neo-arsphenamin can be given intraperitoneally to infants with safety. Although this method is not as rapid as the intravenous injections, the neo-arsphenamin is absorbed with sufficient rapidity to act in any condition. This method is ideal for use in children in whom the small veins make the injection difficult, and the condition is of such degree that active treatment is imperative.

Tuberculosis of the Vagina (Lawrence R. Wharton, M.D., *Journal of the American Medical Association*, July 25, 1925).—Tuberculosis of the vagina is one of the rarest of all gynæcologic diseases. It almost never occurs as the primary manifestation of the disease; at necropsy, in practically every instance older tuberculous lesions have been found elsewhere. The vaginal lesion is not always secondary to tuberculosis of the uterus or Fallopian tubes; in fourteen of twenty-eight cases examined at necropsy the uterus, tubes and ovaries were normal. The treatment and prognosis depend on the activity and extent of the associated tuberculous lesions. Tuberculous ulcers of the vagina rarely yield to conservative treatment, excision is the procedure of choice. In every instance, however, the therapeutic problem is fundamentally medical, and the patient should be treated from that point of view.

Beriberi from a Diet of Raw Starch (*The Journal of the American Medical Association*, August 8, 1925).—The diagnosis of beriberi in the patient described in this paper seems justified because of (1) the history of a prolonged high carbohydrate diet deficient in vitamins; (2) the clinical picture of peripheral neuritis with myocardial failure—the ordinary causes for these conditions having been eliminated, and (3) the rapid response which the patient made to specific therapy. The nephritis is difficult to explain. Beriberi ordinarily does not produce a nephritis. Whether it occurred as an independent condition or as the result of intravenous medication, it is impossible to say. The possibility of some toxic substance in the starch itself, which could produce both a nephritis and a peripheral neuritis, was carefully considered. However, the analysis of gloss starch given in the textbooks, as well as that submitted by the manufacturers of the particular starch in question, makes this possibility very unlikely. The peculiar cardiac findings simulating aortic valve disease afford material for much interesting speculation. Vedder has shown that beriberi is a disease of the entire nervous system, and it seems possible that a paralysis of the vasomotor system, in which the heart was pumping blood into relaxed and dilated arterioles, could give the vascular signs presented by the patient. On the other hand, a relative aortic insufficiency might have occurred as a result of the dilatation of the heart, although if this were true it seems as though a diastolic murmur should have been present.

Meralgia Paræsthetica: Relation to Osteoarthritis of Spinal Vertebræ (*Journal of the American Medical Association*, August 8, 1925).—In the light of the facts given in this paper, the conception that meralgia paræsthetica is a peripheral nerve disease due to trauma, infections, static foot disturbances, or other vague disturbances must be abandoned. A study of twenty-five cases revealed the fact that this affection is radicular in nature and the result of the irritation or compression in the intervertebral spaces or foramina. That this irritation or compression can be attributed to an osteoarthritic process in the vertebræ was confirmed by clinical and Roentgen-ray evidence. Whilst the matter of treatment has not been under consideration, it obviously suggests itself as directing therapeutic efforts toward the cause and not the effects of the affection.

Hexyl Resorcinol. The Development and Clinical Application of a Synthetic Compound Possessing the Experimental Requirements of an Ideal Internal Urinary Antiseptic (Veader Leonard, *Journal of Urology*, December 6, 1924).—Hexylresorcinol, a stable organic substance of known chemical constitution, is the most powerful germicide ever described as a non-toxic substance. As measured by the Hygienic Laboratory method now in use it exhibits an increase in bactericidal power over resorcinol, its mother substance, of more than 15,000 per cent., and over phenol of more than 4,000 per cent. The application of hexyl resorcinol as an internal urinary antiseptic is based upon a logical and orderly development of the chemical and biological characteristics of its lower homologues. Hexyl resorcinol is non-toxic by mouth and its prolonged administration of large repeated doses to animals and to man results in no injury to the kidney or irritation of the urinary tract. It retains its powerful bactericidal action in solution in human urine of any reaction, and is secreted unchanged by the kidney after oral administration in sufficient concentration to impart active bactericidal properties to the urine. No other substance (except its less efficient homologue) has ever been described as possessing these qualifications. The enormous

excess of bactericidal power in hexyl resorcinol is necessary to an internal urinary antiseptic of this type because the bulk of each dose is excreted as an inert conjugate. Otherwise a few milligrams a day, instead of 0·3 to 0·6 grm. three times a day, would be sufficient to insure a practically continuous flow of bactericidal urine. It is highly probable that hexyl resorcinol exerts little, if any, influence on infections which have invaded the parenchyma of the kidney. It is an internal urinary antiseptic. No internal renal antiseptic is known. Urinary infections due to *B. coli* and confined to the urinary mucosa from the kidney pelvis downward can be cleared up completely with no other treatment than hexyl resorcinol by mouth if the bacterial count of the urine is low. If the count is high, as is usually the case in *B. coli* infections, the mass action of the free hexyl resorcinol, excreted in the urine, is insufficient to complete the disinfection until the count is reduced by local treatment. Persistent treatment (thirty to sixty days) is usually necessary in these cases. If the infection has invaded the renal parenchyma, as is usual in cases of long standing, hexyl resorcinol, alone or combined with any known method of treatment, will not complete the disinfection and frequently fails even to influence it. In some of these heavy *B. coli* infections there is, however, very pronounced clinical improvement as evidenced by subsidence of symptoms, macroscopic clearing of the urine, gain in weight, &c., without any apparent reduction in the number of organisms per cubic centimetre of urine. Urinary infections due to the usual Gram-positive cocci ordinarily clear up promptly, completely and permanently with no other treatment than hexyl resorcinol by mouth.

The Use of Fish in the Control of Yellow Fever in Peru (Major Henry Hanson and Lawrence H. Dunn, *Military Surgeon*, September, 1925).—Fish were used in many of the early yellow fever campaigns for the destruction of *Ædes ægypti* larvæ, but nowhere so extensively as in Guayaquil. They were tried and found very efficacious in Peru in 1921, where they were used on the most extensive scale yet employed, and with the most strikingly good results. The early control methods in Peru consisted in throwing out water that contained larvæ; covering containers; limiting the number of containers and requiring an alternation in their use, so that from time to time each receptacle could be turned upside down and allowed to dry; and finally straining once every week or ten days all the water kept in containers. The prevailing types of container were tanks, barrels, botijas and tinajas, with the botijas and tinajas predominating. Experiments with fish were begun early in the year 1921 in Chiclayo, where six local species of fish were tried out for their larvicidal properties and adaptability for use as an anti-*ægypti* measure. Of the six species, two were found to be very satisfactory, the *chaloquoques* and *lifes*, the latter being the best, most readily available, and generally used. Wherever these were distributed in containers the breeding index promptly fell to well below the index of safety against the spread of yellow fever. Nearly a million of them were used.

Current Literature.

INDIAN MEDICAL JOURNAL.
September, 1925.

Notes on Some Methods for Diagnosis of Hookworm Infection and for Estimating the Egg Output (Asa C. Chandler).—The author compares the Kofoid and Barber method of salt flotation and surface looping with Lane's method of direct centrifugal flotation (D.C.F.) for diagnosis of hookworm infection, and considers the former of greater value than the latter. With regard to egg output the following may be quoted: "The substitution of the D.C.F. method for the Stoll egg-counting method for estimating egg output seems to us quite impracticable. Even assuming that with every detail of the technique carefully controlled, 90 per cent. or more of the total eggs can be obtained on a single spin, when this number exceeds one or two hundred, which is more frequently the case than otherwise, the counting of the eggs is very burdensome; and when the eggs exceed five or six hundred an accurate account becomes quite impossible without spreading the drop over a large area or washing the eggs into a measured quantity of fluid and counting the number in a measured fraction, either of which involves time and labour. The results from our egg-counting technique indicate that it is as fully as accurate as the D.C.F. method—even when the latter is pushed to finality—and it is certainly less troublesome in that a single process is suitable for all degrees of infection. Where less than 100 eggs per grm. are present only one or no eggs can be expected on two slides. If there is one egg on two slides an average of fifty is indicated, whereas two negative slides from a stool which has been shown to be positive by a concentrative technique can arbitrarily be regarded as having twenty-five eggs per grm. without involving any great inaccuracy in a group estimate.

The Toxicity of Carbon Tetrachloride to Cats. A Warning (Asa C. Chandler and R. N. Chopra).—From these experiments one can conclude that it is very unsafe to treat feline animals with carbon tetrachloride. These results differ widely from those obtained in 1923 by Hall and Shillinger, who reported ten experiments on five kittens with doses of carbon tetrachloride, and who state that carbon tetrachloride at the rate of 0·3 c.c. per kilo is well tolerated by cats. The authors, in giving carbon tetrachloride to 87 cats, in various doses and under various conditions of diet, &c., found the susceptibility of cats to this drug very great.

Observations on Dementia Præcox (Frank Noronha).—A recognition of the early symptoms of this disease is of importance to the general prac-

titioner, and if the case is taken in hand early there is prospect of rehabilitating the patient and preventing permanent mental breakdown. In the majority of cases there is a history of the patient having run away from home, and in his travels having come in collision with the law and thereby being recognized as insane for the first time. This impulsive act, so characteristic of the disease, leads later on to other irregularities of conduct which finally land the afflicted person into the asylum. Within a few days, or sometimes within the twenty-four hours, of admission into the asylum he shows evidence of the true nature of his malady. A maniacal patient has a ready reason to account for his act, but it is not so with a præcox patient; he has no answer ready when questioned but a bare denial, with a purposeless smile. A point of interest to the general practitioner is that some of these cases in their incipient stages may be mistaken for hysteria or neurasthenia; and that dementia præcox may supervene on a previous hysterical or neurasthenic state. Occupation of a definite character and persuasion are of great help in the treatment of these patients. Although they may resist at first, they could be got round with persistent persuasion, and the effect of work is seen in the improvement in their physical condition and corresponding increase of mental stability.

Experiments in Air Embolism (A. R. D'Abreu).—The conclusions drawn from these experiments are as follows. A few small bubbles of air injected into a vein at a slow rate are apparently harmless, and a like remark would also appear to apply to a small continuous column of air. Twenty-four ounces of air was sufficient to produce the death of a bull weighing approximately 500 lb., so that a man weighing 10 to 11 stone would proportionately take about 6 to 7 oz. as the lethal dose. Rabbits succumb very easily to air embolism, but they are somewhat delicate and susceptible rodents, and human beings might be similarly qualified as their endurance can hardly be compared with that of beasts of the field on whom the experiments were tried. Hence the lethal dose would in reality probably be less than 6 or 7 oz. On the other hand, the velocity of the circulation and pulse-rate (45 per minute) in oxen are both slower than in man, and the specific gravity of their blood, which is 1,060, or slightly more, is higher than in man, the three being qualities likely to give a greater susceptibility to the effects of air emboli, although their endurance may be greater than man's. The first noticeable symptoms were produced when 8 oz. of air was injected. Assuming this quantity to be the dangerous limit for animals used, then working it out proportionately, a volume of 2 oz and 2 dr. is considered unsafe for man.

Blood of a thicker consistency, i.e. of a higher specific gravity than the normal of 1.056, must flow through the vessels with difficulty and be more prone to clot around air globules. If, therefore, in disease the specific gravity of the blood goes up with a retardation of the flow, then the admission of air into the veins should be carefully guarded against. In those diseases in which the coagulability of the blood is increased these precautions should also be taken. When severe hæmorrhages have taken place the blood coagulates quicker than normally, and in these cases also the entry of air during intravenous transfusions should be especially excluded. In such cases, before any quantity of fluid has been transfused, a large air embolus entering the feebly acting right heart would be likely to further embarrass its action, causing clotting and death, which might easily be put down to the original progressing collapse. In anticipation of these accidents with air emboli of large size some antidote in the form of an injection for immediate use, to reduce the coagulability of the blood suggests itself.

Treatment of Some Abdominal Conditions with Inflation of Oxygen Gas (R. S. Grewal).—The treatment of abdominal conditions with inflation of oxygen gas has been used with great success at the Civil Hospital, Maymyo, during the past few months. The advantages of the operation are: It can be done in subjects who have lung complications and also when the use of chloroform is not safe. Very few instruments are required. There is no danger. It can be done even in small hospitals. Results are good.

Action of Disinfectants on Microbes: An Interesting Phenomenon (H. Gosh).—During the course of experiments to find out whether by increasing the time of contact of bacteria and disinfectants the rate and extent of growth of the former declined or increased, it was found that certain bacteria showed some growth after one hour of contact with a disinfectant, but produced no growth after three to five hours of contact. After twenty-four or forty-eight hours of contact, however, a few colonies appeared at first, but gradually the number increased as the time of contact was increased. The technique followed is described and three charts accompany the paper.

"Stibosan" (Von Heyden "471") in Private Practice (Sudhir Kumar Das).—The author has used "471" in the treatment of kala-azar and considers it much better in its effects than all the other antimony compounds on the market. It checks the fever with great rapidity; in the cases reported, the average number of injections required to check the fever was three. The duration of the treatment is very short and the patient is, therefore, invalided for a short period only. There is rapid reduction in the size of the spleen. The spleen at first becomes thinned out, then diminishes in size, and from the fifth injection reduces rapidly. No untoward effects have been noted. No vomiting occurred after injection, and no pulmonary complications occurred. In one case the patient had been suffering from piles, heart trouble (a systolic bruit in the mitral area), and was anæmic. After three injections the bruit disappeared and the piles were cured when the injections were completed. The only drawback of this drug is its price; it is too expensive for the poor, and it is amongst the poorer classes that the disease is commonest.

Original Communications.

SOME OBSERVATIONS AND EXPERIMENTS ON *GONGYLONEMA* IN NORTHERN ITALY. A PRELIMINARY NOTE.

By H. A. Baylis, M.A., D.Sc., T. C. Pan, M.B., Ch.B., and Juliet E. B. Sambon.

A number of insects collected by one of us (H.A.B.) and by Dr. L. W. Sambon on an expedition to the Trentino in the autumn of 1924, and numerous others collected in the same region during the present summer (July-September, 1925) have been dissected with a view to discovering the intermediate hosts of *Gongylonema* in Northern Italy. Altogether more than 1,300 insects have been carefully examined. Of these nearly 900 were what may be called "household insects"—i.e., cockroaches, meal-worm beetles, cellar-beetles and other forms that inhabit human dwelling-houses or the stables, cow-sheds and fowl-houses in immediate proximity to them. In none of these were we able to demonstrate the existence of larvæ of *Gongylonema*, although the larvæ of certain other Nematode and Cestode worms were occasionally found in them. The following table shows the numbers and localities of the more important kinds of household insects studied.

Table I.—Household Insects.

	Villa Lagarina	San Michele	Lavis	Coredo	Mezzana	Calavino	Vigo di Fassa	Valda	Castello	Grumes	Lases	Canezza	Castiglione di Cervia
Blatta orientalis	222	—	4	—	—	—	2	—	—	—	—	—	—
Blattella germanica	—	9	3	10	32	12	6	51	50	164	—	—	—
Tenebrio molitor (imago and larva)	2	—	—	—	—	—	—	51	—	—	—	—	—
Tenebrio obscurus (imago and larva)	59	—	54	—	—	—	—	—	—	—	—	--	—
Blaps lethifera (imago and larva)	34	—	29	—	—	—	—	20	—	—	15	3	31

In addition to the species mentioned in the table, a few specimens of other insects, such as the larvæ of meal-moths (*Ephestia*) and of *Dermestes*, were also dissected, with equally negative results.

A large proportion of our work was centred in the village of Villa Lagarina, which lies in the Valley of the Adige near Rovereto. As it was found that practically all the local cattle slaughtered in this district were infected with *Gongylonema*[1], and as the larvæ of the cattle form of *Gongylonema* had been found in America by Ransom and Hall (1915) in certain dung-beetles of the genera *Aphodius* and *Onthophagus*, we next turned our attention to these insects.

[1] While common in the lower valley of the Adige, *Gongylonema* infection of cattle appears to be rare or absent in the region of the Upper Adige and in the valleys of La Pusteria.

Having found certain spots to which the cattle of Villa Lagarina were taken to graze, we collected as many dung-beetles as possible from the fresh cow-dung in these places. The beetles were all identified by Mr. K. G. Blair, of the British Museum (Natural History). The most abundant species was *Onthophagus taurus*, and next to it in numbers was *Caccobius schreberi*. Of the beetles collected in this locality 450 were dissected, and in a certain percentage of them encysted larvæ corresponding to those of *Gongylonema* were found. The following table (Table II) gives the number of each species dissected, and the number found positive for *Gongylonema* larvæ.

Table II.—Dung-Beetles.

	Total examined	Positive for Gongylonema
Onthophagus taurus L.	200	7
Onthophagus furcatus F.	22	—
Onthophagus opacicollis Reitt.	12	—
Caccobius schreberi L.	55	2
Aphodius fimetarius L.	21	—
Aphodius hæmorrhoidalis L.	37	1
Aphodius subterraneus L.	63	—
Gymnopleurus sturmi Macleay	22	—
Oniticellus fulvus Goeze	45	2
Sphæridium bipustulatum F.	36	—
Histeridæ (3 species)	13	—

So far as can be judged from the small figures available, it appears that between 3½ and 5 per cent. of certain species of dung-beetles (*Onthophagus taurus*, *Caccobius schreberi*, *Aphodius hæmorrhoidalis*, *Oniticellus fulvus*) in this locality are infected with *Gongylonema*. In all probability both the incidence of infection and the number of species infected are higher. The larvæ may have been frequently overlooked owing to their small size and the difficulty of examining every part of the beetles; while the number of specimens dissected is, in many cases, regrettably small.

The dung-beetles mentioned are the only insects which may certainly be regarded as intermediate hosts of *Gongylonema* in this part of Italy. They occur, not in the houses, stables, or cow-sheds, but in the open. Our specimens, as has been mentioned, were all collected from cow-dung. No other animals besides cattle appeared to have grazed in the places where they were collected, and since a high percentage of the local cattle is infected

with *Gongylonema*, there is a strong presumption that the larvæ found belonged to the cattle form of *Gongylonema*.

So far as we are aware, no information exists as to the intermediate hosts of the cattle *Gongylonema* in Europe, and we believe that this is the first occasion on which systematic search has been made for them. In the United States of America the following dung-beetles are known to serve as intermediate hosts (Ransom and Hall, 1915): *Aphodius femoralis*, *A. granarius*, *A. fimetarius*, *A. coloradensis*, *A. vittatus*, *Onthophagus hecate* and *O. pennsylvanicus*. It is not quite clear from Ransom and Hall's paper whether *Aphodius congregatus* and *A. inquinatus* were definitely found to be infected. In Algeria, Seurat (1916) has recorded the finding of larvæ which he attributes to *Gongylonema scutatum* in *Blaps appendiculata*, *B. strauchi* and another species of *Blaps*. Ransom and Hall (1917),

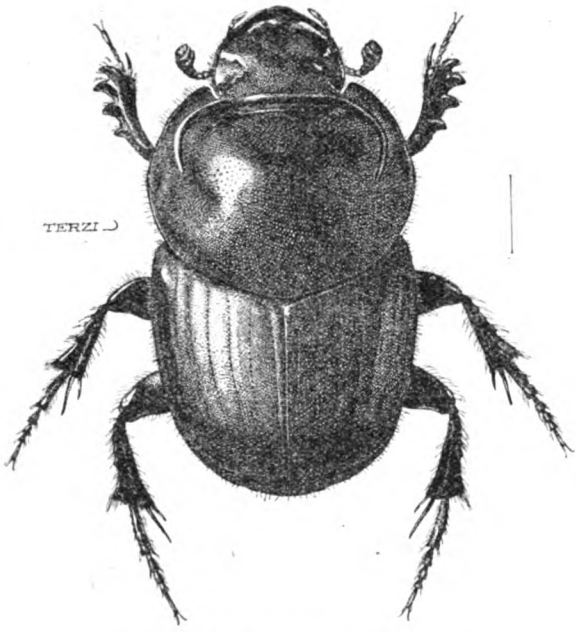

FIG. 1.—*Onthophagus taurus*. ♂.

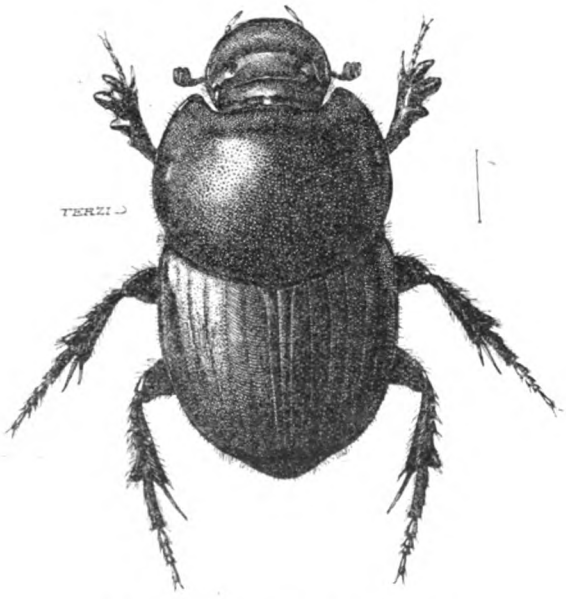

FIG. 2.—*Onthophagus taurus*. ♀.

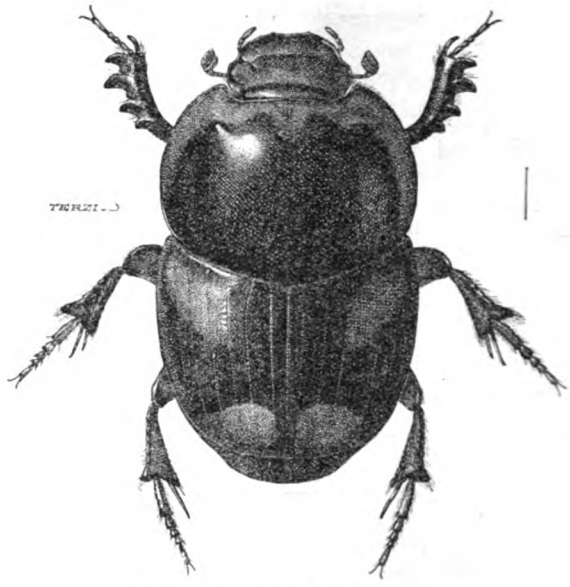

FIG. 3.—*Caccobius schreberi*.

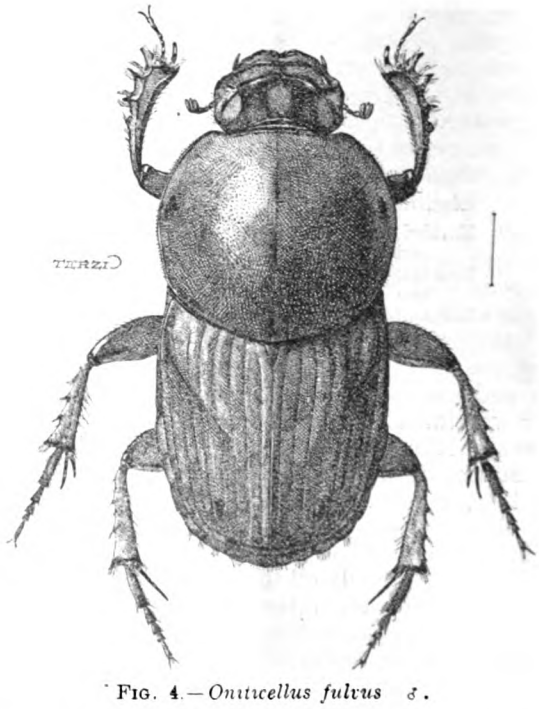

FIG. 4.—*Oniticellus fulvus* ♂.

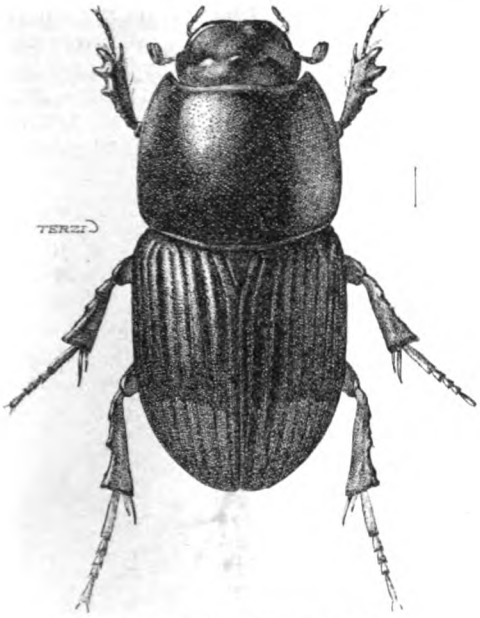

FIG. 5.—*Aphodius hæmorrhoidalis.*

FIG. 6.—Photomicrograph of an encapsuled larva (third stage) of *Gongylonema* from *Onthophagus taurus.* (× 70.) The capsule is in intimate connection with branches of the host's tracheæ and portions of the fat-body.

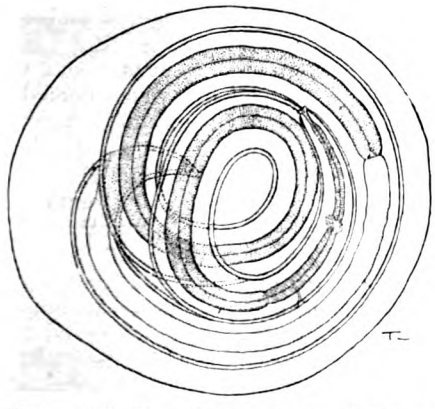

FIG. 7.—Encapsuled *Gongylonema* larva (third stage) from *Onthophagus taurus.* (× about 100.)

however, doubt the correctness of the specific determination of Seurat's larvæ, and are of the opinion that they did not belong to *G. scutatum* but to some other species. The constant absence of *Gongylonema* larvæ from the *Blaps* dissected by us in Italy supports this contention.

On the other hand, Seurat has recorded the occurrence in various Algerian dung-beetles (*Ateuchus sacer, Onitis irroratus, Onthophagus bedeli, Geotrupes douei, Gymnopleurus mopsus* and *G. sturmi*) of larvæ which he considers to be those of *Gongylonema mucronatum* Seurat, 1916, of the hedgehog. Ransom and Hall suggest that these may in reality have been the larvæ of the cattle form, and on comparing Seurat's measurements of these larvæ with those given by Ransom and Hall for their American larvæ, this seems highly probable.

Experimental Infection of Cockroaches.

It is well known that the larvæ of *Gongylonema neoplasticum* of rodents occur naturally, in certain localities, in the large American cockroach, *Periplaneta americana,* and sometimes in the common *Blatta orientalis* (Fibiger and Ditlevsen (1914), Wassink (1916)). They have also been experimentally transmitted by Fibiger both to *Blatta orientalis* and to *Blattella germanica.* The larvæ of the cattle *Gongylonema* have been successfully transmitted by Ransom and Hall (1915, 1917) not only to *Aphodius,* but also to *Blattella germanica.* The latter insect was also infected by them by feeding with the eggs of *Gongylonema* from the pig.

No attempt appears to have been made hitherto to infect *Blatta orientalis* with the cattle form of *Gongylonema.* Experiments carried out by us in Italy appear to show that while the infection of *Blattella* with this worm is easily brought about, it is difficult, if not impossible, to produce it in *Blatta.* Several batches of *Blatta orientalis* were fed repeatedly with eggs of *Gongylonema* taken from the œsophagi of cattle or sheep. The female worms were cut into small pieces in tap-water, and crumbs of bread were soaked in the mixture thus obtained. The technique was thus similar to that of Ransom and Hall (1917), except that tap-water was used instead of physiological salt solution. On dissecting a number of these cockroaches, taken at random, at intervals of from two to five weeks after the first feeding, no larvæ of *Gongylonema* were found, either encapsuled or free, in any part of the insects. On examining the intestines of the cockroaches, or their fæces, from one to four days after feeding with eggs, it was not difficult to find both unaltered eggs and empty shells whose polar caps had come away completely or had, in rare cases, been perforated. Living larvæ were not observed.

The result of a similar experiment with *Blattella germanica* was quite different. Twenty of these insects were fed four times (August 2, 7, 12, 21) with eggs of the cattle *Gongylonema.* On the third day after the first feed five of them were found dead, but nothing of interest was discovered in them on dissection. On August 20 (eighteen days after the first feed, thirteen days after the second

feed and eight days after the third feed) one *Blattella* was killed and dissected. Several young *Gongylonema* larvæ, apparently at the second stage, but already encapsuled, were found in its abdominal cavity. On the following day (August 21) a fourth feed of eggs was given to the remaining cockroaches. On August 31 (twenty-nine days after the first feed and ten days after the last feed) another cockroach was killed and dissected. It was found to contain twenty-seven fully-developed third-stage *Gongylonema* larvæ.

Experimental Infection of Rats.

(1) As a measure for controlling the entirely negative results of the dissection of cockroaches from houses in Villa Lagarina, seven rats[1] were fed on *Blatta orientalis* from two of the houses from which the largest number had been dissected.

Two rats were fed with fifty of the insects on August 11 and with a similar number on August 14. Their fæces were examined at intervals both before and after the experimental feeding, but never showed any eggs of *Gongylonema*. On November 4 the two rats were killed and carefully dissected, not only the stomach, but the œsophagus and mouth being thoroughly examined, but no *Gongylonema* was found in them. Two more rats received two feeds of fifty *Blatta* from the same house on August 16 and 18 respectively, and were similarly negative when dissected on November 2. Three rats received a feed of forty-six *Blatta* from the second house on August 20, and were negative for *Gongylonema* when dissected on November 10.

(2) An attempt was made to infect three rats with the *Gongylonema* of cattle. The experiments were as follows:

(*a*) One rat received, on August 8, 10, 14 and 16, four feeds, each containing twenty-five *Onthophagus taurus* from the infected stock at Villa Lagarina. When killed and dissected on October 27 it showed no sign of infection with *Gongylonema*.

(*b*) Two other rats received *Gongylonema* larvæ, at the third or infective stage, isolated by dissection, as follows:

Rat A received a single larva from *Caccobius schreberi* on July 22. This was injected into its mouth with water by means of a pipette. On August 2 it received in the same way three larvæ from *Onthophagus taurus*. Rat B received, on August 17, four larvæ from *Caccobius schreberi*. On August 31 these two rats (which were kept together) received between them 16 larvæ from an experimentally-infected *Blattella germanica* (see previously described experiment). The larvæ, in this instance, were placed in water on two small square pieces of bread. This method did not, however, result, as was hoped, in an equal sharing

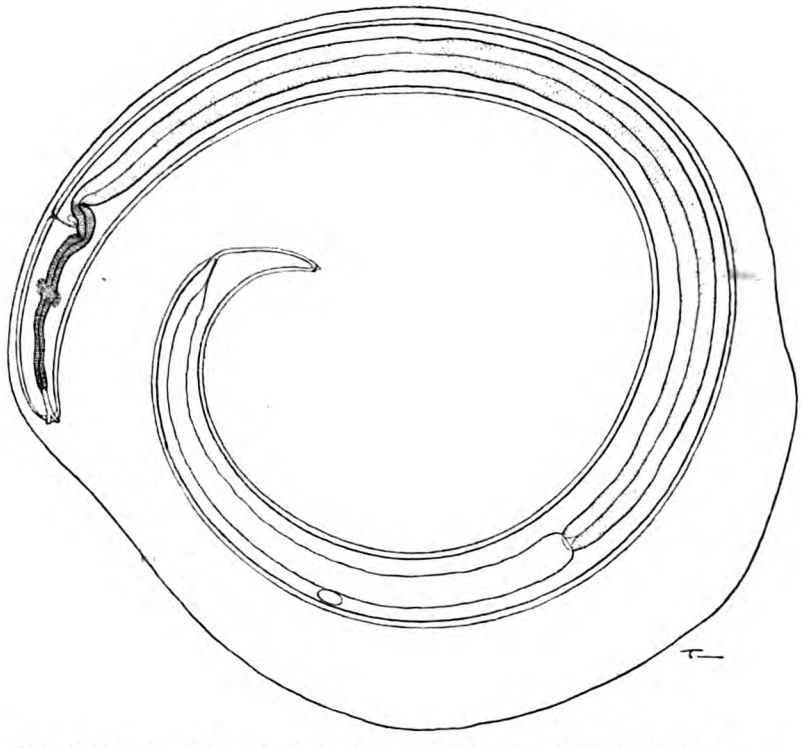

Fig. 8.—Encapsuled *Gongylonema* larva (third stage) from *Onthophagus taurus*. (× about 110.)

[1] The rats used in these experiments have been determined by Mr. M. A. C. Hinton as tame varieties of *Rattus norvegicus*.

of the meal, for rat B consumed nearly the whole of one piece and about half of the other, rat A, therefore, receiving very few, if any, of the larvæ. The fæces of both animals remained negative

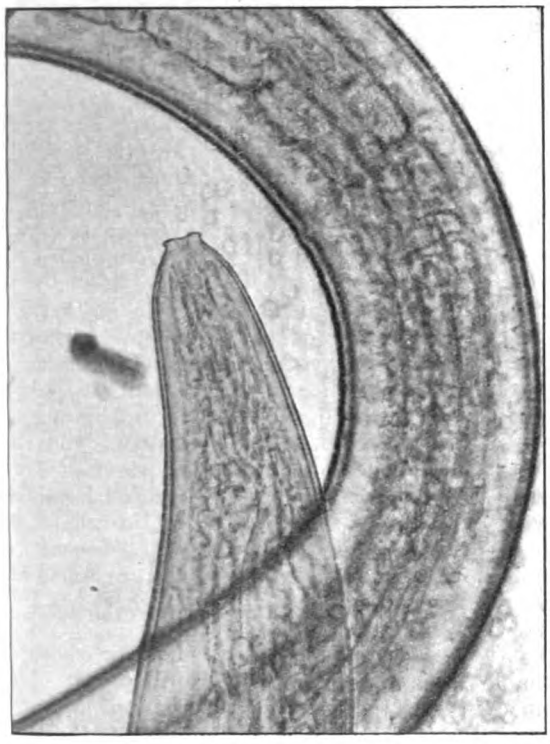

FIG. 9.—Photomicrograph of the head of a *Gongylonema* larva (third stage) from *Oniticellus fulvus*. (× 400.)

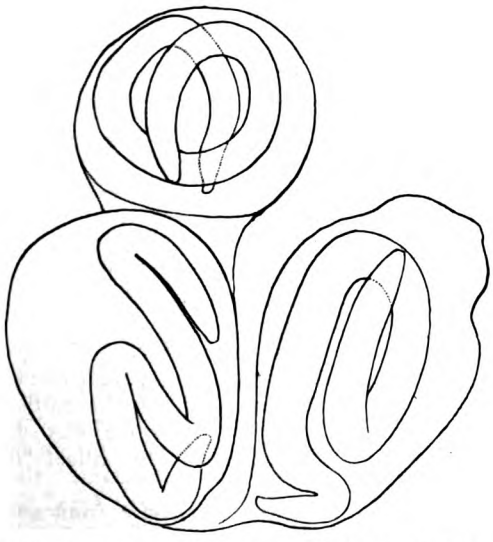

FIG. 10.—A group of three encapsuled second stage larvæ of the *Gongylonema* of cattle, from the body-cavity of an experimentally-infected *Blattella germanica*. (× about 100.)

for *Gongylonema* eggs, though examined repeatedly up to November 12. On November 16 (seventy-seven days after the last feeding) both rats were killed and dissected, and a single *Gongylonema* was found in the œsophagus of each. The stomach and mouth were, in each case, free from signs of infection. The worm in rat A was a male, which had a left spicule measuring 4·9 mm. in length. The worm in rat B was a small and apparently immature female.

Thus two out of three rats appear to have been successfully infected, though the infection was slight compared with the number of larvæ given

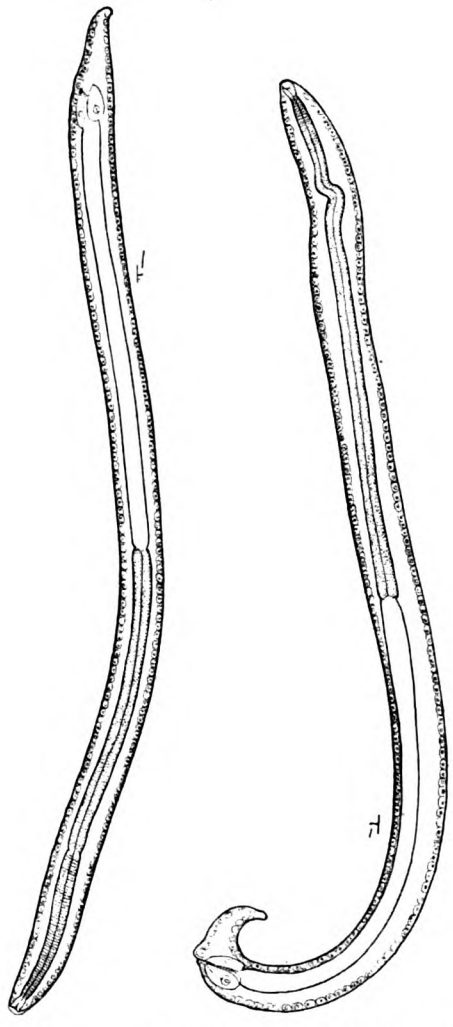

FIG 11.—Two second stage larvæ of the *Gongylonema* of cattle, from an experimentally-infected *Blattella*, removed from their capsules. (× about 110.)

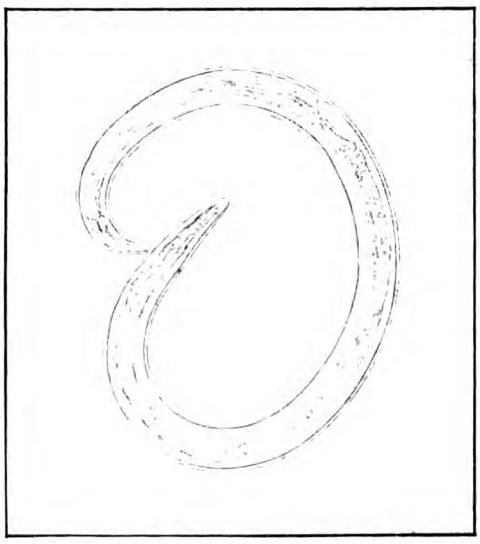
to them. That the worms were actually derived from the larvæ experimentally administered, and that they belonged to the cattle form and not to the usual rat form of *Gongylonema* seems fairly certain from the following considerations. (1) Every reasonable precaution had been taken to guard against possible infection with the rat form, the rats used having been young animals specially taken out from England for the pur-

pose of these experiments, and having been kept in a place where they were not likely to come in contact with cockroaches or other insects.



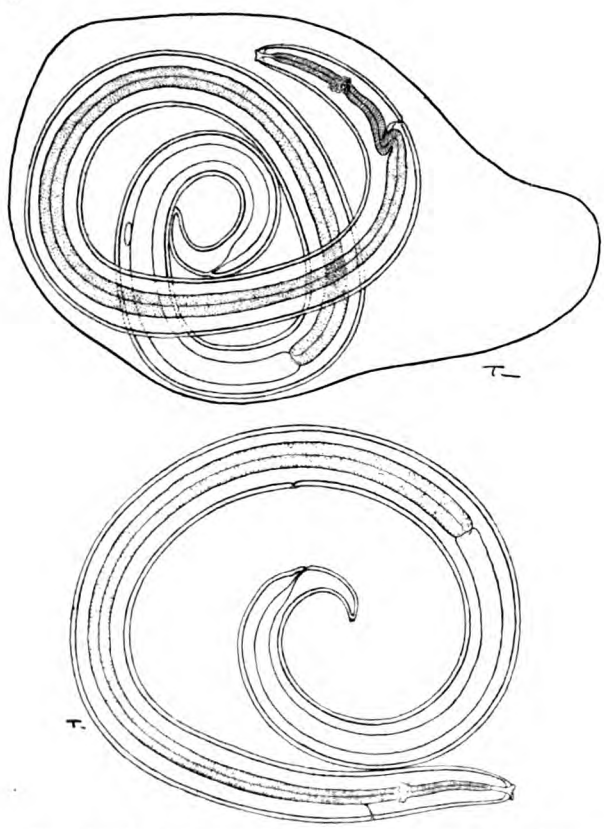


FIG. 12.—Photomicrograph of a third stage larva of the *Gongylonema* of cattle, from an experimentally-infected *Blattella*, removed from its capsule. (× 70.)

FIGS. 13 and 14.—Two third stage larvæ of the *Gongylonema* of cattle, from an experimentally-infected *Blattella*. (× about 100.) One larva is still enclosed in its capsule, the other has been liberated.

Further, their fæces had been examined repeatedly before the experiment. (2) Of a considerable number of wild rats obtained locally and dissected, none showed infection with *Gongylonema*. (3) None of the other rats kept near these two (all belonging to the same stock and being kept under the same conditions) showed any sign of infection either on fæcal examination or on dissection. (4) The worms were found in the œsophagus and not in the stomach, the latter being the more usual situation for the *Gongylonema* of rats. (5) The length of the left spicule of the male worm greatly exceeds the maximum hitherto recorded for *G. neoplasticum* (0·67 mm.), but is much more comparable with the minimum recorded for the *Gongylonema* of ruminants (5·0 mm.).

The experiment indicates, therefore, that it is possible for rodents to acquire infection with the form of *Gongylonema* considered by some authorities to be confined to ruminants. The only previous experiment known to us bearing on this question is one in which Ransom (see Ransom and Hall, 1915), on two occasions, fed a white mouse with *Gongylonema* larvæ apparently obtained from dung-beetles in the United States. The mouse was killed only twenty-eight days after the second feeding, and the fact that no worms were found in it may possibly have been due to the shortness of the time allowed for their development.

We take this opportunity of acknowledging the valuable assistance rendered, during part of the period, in the tedious work of dissection by Mr. K. G. Blair, B.Sc., F.E.S., and Mrs. C. Bonne.

We are also greatly indebted to Dr. A. L. Sheather for his excellent photomicrographs of some of our preparations, and to Mr. Terzi for the drawings which he has executed with his well-known skill and accuracy.

SUMMARY.

(1) Household insects, such as *Blatta*, *Blattella*, *Blaps*, *Tenebrio* and *Ephestia*, were not found to be naturally infected with *Gongylonema* in Northern Italy.

(2) Four species of dung-beetles (*Onthophagus taurus*, *Caccobius schreberi*, *Aphodius hæmorrhoidalis* and *Oniticellus fulvus*) were found to be naturally infected with larvæ of *Gongylonema*, presumably of the cattle form. No other natural intermediate hosts for *Gongylonema* were discovered.

(3) By feeding with the eggs of the cattle form of *Gongylonema*, *Blattella germanica* was successfully infected, but attempts to infect *Blatta orientalis* failed.

(4) Rats fed on *Blatta orientalis* from some of the houses concerned did not become infected with *Gongylonema*, thus confirming the negative results of dissection of the insects.

(5) Two rats were experimentally infected with the *Gongylonema* of ruminants by feeding them with larvæ obtained by dissection from the intermediate hosts.

A NOTE ON THE FLAGELLATES OF ANOPHELINES AND CULICINES PREVIOUSLY MENTIONED IN THE LITERATURE WITH A DESCRIPTION OF A CRITHIDIAL FORM IN A NEW HOST *ANOPHELES UMBROSUS* FROM THE FEDERATED MALAY STATES.

By J. G. THOMSON, M.A., M.B., Ch.B.,

Director of Protozoology, London School of Hygiene and Tropical Medicine,

AND

ANDREW ROBERTSON, M.B., Ch.B.,

Assistant in Protozoology, London School of Hygiene and Tropical Medicine.

MATERIAL AND ACKNOWLEDGMENTS.

THE material, on which the description of the organism was based, was very kindly presented by Dr. H. P. Hacker, who, while making a field examination of female anophelines in the Federated Malay States for the presence of malarial oöcysts and sporozoites, found the flagellates in Giemsa-stained preparations of the gut contents of two female *Anopheles umbrosus*. A smear of the salivary gland of one of these mosquitoes also showed numerous flagellates.

An examination of the literature shows that these organisms are common in mosquitoes, and may possibly occur in most species. For example, flagellates have been reported in *Culex fatigans*, *Culex pipiens*, *Culex sylvestris*, *Culex triseriatus*, *Culex richardii*, *Anopheles paludis*, *Anopheles maculipennis*, *Anopheles stephensi*, *Theobaldia annulata*, *Anopheles nili*, *Anopheles superpictus* and *Stegomyia fasciata*. It is of interest, therefore, to report them in another host, viz., *Anopheles umbrosus*, but, while the forms seen and studied are crithidial flagellates capable of comparison morphologically with those described by other workers, it is unfortunately impossible, without further observations on the morphology and life-history, to correctly define their generic and specific identity.

THE GENERIC IDENTITY OF INSECT FLAGELLATES.

The common occurrence of flagellates belonging to the family Trypanosomidæ in blood-sucking and non-blood-sucking insects and arachnids all over the world is now well known, and is a factor of considerable importance in the investigation of the transmission of trypanosomiasis and leishmaniasis in man and animals. These insect flagellates may be placed in three groups: (1) Natural flagellates transmissible from insect to insect, which, as far as is known, are incapable of infecting man or animals. (2) Flagellates, which are the developmental stages of trypanosomes or leishmania, and are capable of infecting man and animals. (3) Flagellates whose habitat is the latex of certain plants, but which are also present in the gut of plant-sucking hemiptera.

Some confusion has arisen regarding the nomenclature of these flagellates, and new generic and specific names have been applied to them before their complete life-histories were known. Different specific names even have been given to organisms morphologically identical merely because they have occurred in separate hosts. Wenyon (1913) suggested a useful method of classifying generically these flagellates of insects, which is based both on the morphology and also on the life-history of the parasite. The adoption of this method would help to avoid confusion.

GENERIC CLASSIFICATION OF INSECT FLAGELLATES.

(1) Genus *Leptomonas*. Type *Leptomonas bütschlii* Kent, 1881.

The name was applied to a uniflagellate organism from *Trilobus gracilis* (a nematode). The body is trypaniform in shape, the nucleus more or less central, and the single flagellum arises in a blepharoplast near a parabasal body situated at the anterior extremity. There is never at any time in its history an undulating membrane. Ovoid leishmania-like bodies are formed, passed in the insect's fæces, and serve as the transmitting forms to other insects. As far as evidence is available these are true insect flagellates, and incapable of producing infection in vertebrates. The different species of *Leishmania* in man and animals produce in culture typical leptomonad forms.

The type species, *Leptomonas bütschlii*, has never been redescribed.

(2) Genus *Leishmania* Ross, 1903. Type *Leishmania donovani* Laveran and Mesnil, 1903.

In the vertebrate host these are ovoid bodies showing, in well-stained specimens, nucleus, parabasal body, blepharoplast and rhizoplast, but no free flagellum. In culture they develop into typical leptomonads, which undoubtedly represent a stage in the life-history in a transmitting insect. For this reason any leptomonad flagellate in an insect requires careful investigation.

(3) Genus *Crithidia* Leger, 1902, emend. Patton, 1908. Type *Crithidia fasciculata* Leger, 1902.

These are characterized by elongated bodies when fully developed. The nucleus is more or less central. Parabasal body and blepharoplast are situated close to the nucleus but anterior to it. The flagellum runs along the anterior margin of the body, form-

ing, in many cases, an undulating membrane. Trypanosome forms are never seen. These are common in insects, and the developmental forms of trypanosomes always show this type in the insect host. Many of them seem to be true insect parasites.

(4) Genus *Herpetomonas* Saville Kent, 1881. Type *Herpetomonas muscarum* (Leidy, 1856) Kent, 1881. (Syn. *Herpetomonas muscæ domesticæ*.)

This seems to be a true insect flagellate, and its developmental forms in the gut of the fly show leptomonad, crithidial, trypanosome and leishmania forms. These forms, encountered by different observers, have led to confusion, but the work of Rosenbuch (1910), Alexeiff (1911), Dunkerly (1911) and Wenyon (1913) has definitely established the fact that the various forms seen are merely stages of the development of a single genus, namely, *Herpetomonas*, which appears to be a true insect flagellate.

(5) Genus *Trypanosoma* Gruby, 1843. Type *Trypanosoma rotatorium* (Gruby) Mayer, 1843.

This is a parasite of animals. The body is elongated, nucleus more or less central and the parabasal body and the blepharoplast are posterior in position to the nucleus, and the flagellum runs along a well-defined undulating membrane. The developmental forms in the insect host may show leptomonad, crithidial, leishmania and trypanosome forms.

From the above classification one sees that it is impossible to assign a generic name to any of these flagellates before the complete morphology and life-history has been studied. A useful and striking example of the necessity for this careful study is well illustrated by the recent work of Hoare (1923) on *Trypanosoma melophagium*. For years numerous authorities regarded *Crithidia melophagia* Flu, 1908, as a natural flagellate of the sheep ked *Melophagus ovinus*. Hoare, however, showed that not only did crithidial forms occur in the ked's gut, but also leptomonads, leishmania forms and metacyclic trypanosomes. He further proved that clean sheep could be infected with a trypanosome by crushing infected keds in their mouths, and thus established the fact that the well-known crithidial forms were simply developmental stages of the genus *Trypanosoma*.

Specific Identity of Insect Flagellates.

In fixing the specific identity of a flagellate the morphology is certainly of great assistance, but it has to be considered that, in different culture media and in different hosts, certain physiological variations may occur, which might materially alter the morphology of a single species. Slight morphological differences in size and shape between two parasites in separate hosts are scarcely grounds enough for assigning new specific names. It may be necessary in all cases to conduct experimental infections of different hosts with the same flagellate in order to establish definitely its specificity.

A good example illustrating the above is seen in recent observations on *Herpetomonas muscarum* of the common domestic fly. Alexeieff (1913) pointed out that workers, in finding a *Herpetomonas* in a new host, assumed, therefore, it was a different species, and, as a result of this, there are in the literature numerous species, which, morphologically, are indistinguishable, e.g., *Herpetomonas muscarum* (Leidy, 1856), Kent, 1881. *Leptomonas drosophilæ*, Chatton and Alilaire, *Leptomonas pycnosomæ*, Roubaud, *Leptomonas ampelophilæ*, Chatton and Leger, *Herpetomonas luciliæ* Strickland, *Herpetomonas calliphoræ* Swingle, *Herpetomonas homolomyiæ* Brug, *Herpetomonas sarcophagæ* Prowazek.

Recently Becker (1923) has shown experimentally that *Herpetomonas muscarum* can infect *Musca domestica*, *Phormia regina*, *Lucilia sericata*, *Sarcophaga bullata*, *Cochliomyia macellaria* and *Calliphora erythrocephala*, and, by cross infection experiments with *Herpetomonas muscarum*, has also shown that *Herpetomonas muscarum*, *Herpetomonas luciliæ*, *Herpetomonas calliphoræ*, *Herpetomonas sarcophagæ* and *Herpetomonas* from *Phormia* and *Cochliomyia* probably represent the same species in different hosts.

Flagellates Noted by Various Observers in the Alimentary Tract of Mosquitoes.

The observations made above regarding the necessity for careful investigations of the morphology and complete life-histories of the flagellates in insects apply particularly to those found in mosquitoes. Many workers have encountered them during various researches, but, beyond the fact that they have recorded their presence, little information of a complete nature, except in a few instances, has been recorded.

Ross (1898) in a preliminary report on his investigations into malaria noted the presence of flagellates in mosquitoes, and, in 1906, he published an interesting communication drawing attention to his earlier observations. He encountered organisms with a single flagellum in several species of *Culex* and especially in the larvæ, pupæ and imagines of *Culex fatigans*.

They were also noted in anophelines.

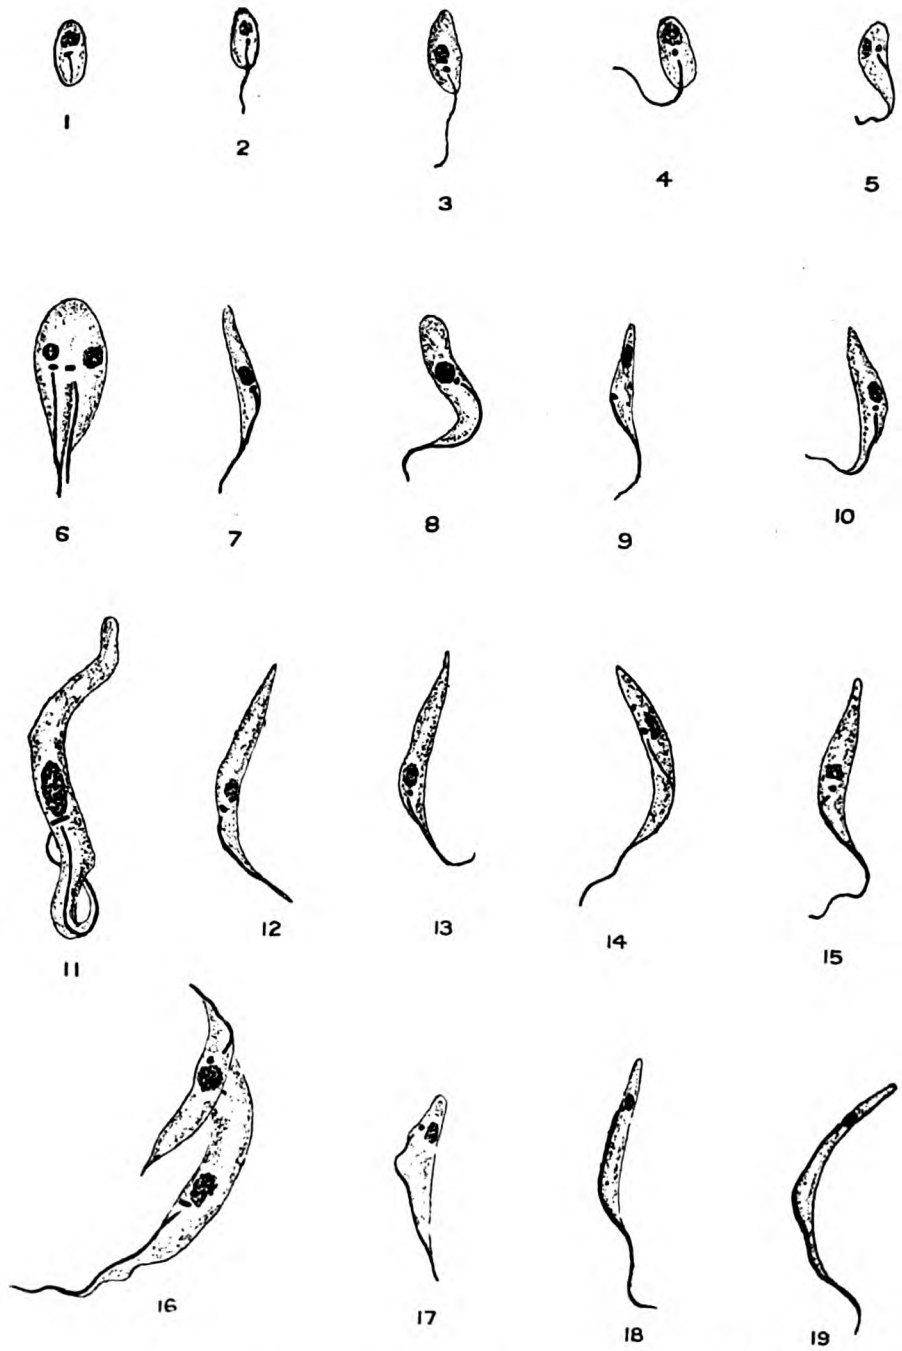
Chatterjee (1901) on dissecting different anophelines found flagellates which he noted were like trypanosomes, and, in 1901, Christophers found heavy infections with similar organisms in a large percentage of anophelines and culicines, which he examined. He found these in the hind gut and rectum.

Durham (1902) in his memoir on yellow fever reported their presence in abundance in *Stegomyia fasciata*, which had fed upon a small cat.

Léger (1902) gives us the first descriptions with diagrams of a flagellate organism he found in the gut of *Anopheles maculipennis*. He named it a

new genus and species, *Crithidia fasciculata*, and this, with the description emended by Patton, is the type species of the genus *Crithidia*. Léger depicts two forms, one long, trypanosome-like, measuring 8 to 14 microns long, and one short, shaped like a barley grain, 3 to 4 microns long, but sometimes as long as 6 to 8 microns, with a flagellum almost the same length as the body. In the longer forms the flagellum took origin in a blepharoplast situated near the nucleus and anterior to it, and ran along closely applied to the edge of the body becoming free for a short distance at the anterior extremity. Léger and Duboscq (1902) again found the same organism in the gut of anopheline larvæ and the adults of *Anopheles maculipennis* in mid-winter in Corsica. Stephens and Christophers (1903) in the first edition of their text-book on malaria stated that flagellates frequently occurred in enormous numbers in the hind gut and rectum of mosquitoes, and, in the second edition (1904) they stated that, when stained, these resembled the developmental forms described by Schaudinn in *Trypanosoma noctuæ*.

Schaudinn (1904), on feeding *Culex pipiens* on *Athene noctua* (the little owl), found trypaniform flagellates and spirochætes in the gut of the mosquitoes, and he wrongly assumed that these were stages in the life-history of *Hæmoproteus* (*Halteridium*) *noctuæ*. His figures depict typical trypanosome forms, and, in view of the work of Woodcock (*vide infra*), it is possible these are developmental forms of *Trypanosoma noctuæ*, but until transmission experiments are carried out this is still *sub judice*.



Lingard and Jennings (1906) found flagellates in *Culex* larvæ, and gave figures. From these it cannot be determined whether they were dealing with leptomonads or crithidia. In the same year Ed. and Et. Sergent (1906) noted and depicted leptomonads in 11 per cent. of the *Culex pipiens* examined and in one specimen of *Stegomyia fasciata* which were raised from larvæ in the laboratory. These they named *Herpetomonas algeriense*. The motile forms often occurred in large numbers in the first part of the hind gut. The body measured 12 to 15 microns and the flagellum 3·5 to 6 microns. In the same communication they reported from the larvæ of several anophelines and of one *Culex* and also in the nymph of a single specimen of *Anopheles maculipennis* a very long narrow leptomonad, which, they stated, resembled *Herpetomonas jaculum* of *Nepa*. The body of this was 16 by 3·5 microns, and the flagellum 24 microns in length.

Novy, McNeal and Torrey (1907) described two flagellates differing in morphology, namely *Trypanosoma* (*Herpetomonas*) *culicis* and *Crithidia fasciculata* in *Culex pipiens*, *Culex sylvestris* and *Culex triseriatus*. In one series of mosquitoes 55 had crithidial forms only, 52 had herpetomonads only, and 19 had both. These observers, however, have confused the generic names. *Trypanosoma* (*Herpetomonas*) *culicis* is really a *Crithidia*, and *Crithidia fasciculata*, according to Woodcock (1914) is not identical with Léger's organism, but is a leptomonad (*vide infra*). These flagellates should, therefore be known as *Crithidia culicis* Novy, McNeal and Torrey, 1907, emend Woodcock, 1914, and *Leptomonas fasciculata* Novy, McNeal and Torrey, 1907, Léger 1902, emend Woodcock 1914. The dimensions of *Crithidia culicis* were 7 to 35 microns by 1·5 to 3 microns, and the total length with flagellum 10 to 45 microns. Those of *Leptomonas fasciculata* were 3 to 4 microns by 2 microns, the organism being pear or cigar-shaped. Larger forms of this latter were about 8 microns with a free flagellum 2 to 5 microns in length. Adie (1907) noted flagellates in *Culex fatigans* and *Culex* sp., and in the same year Dutton, Todd and Tobey found clusters of bodies in the thoracic tissues of a female mosquito, *Anopheles paludis*. These bodies were club-shaped, and, when examined in salt solution, developed a flagellum. It is not possible to determine the flagellate from their description.

Mezinesco (1908) recorded *Crithidia fasciculata* of Léger in *Culex richardii* and *Crithidia culicis* of Novy, McNeal and Torrey on two occasions. Wenyon (1908) encountered crithidial forms in *Anopheles nili*, and in 1911 he found leptomonads in the larvæ and adults of *Stegomyia* sp. (probably *Stegomyia fasciata*). Patton (1912) noted the presence of leptomonads and crithidial forms in *Culex fatigans*, *Culex* sp., and *Anopheles stephensi* in Madras. He found *Herpetomonas culicis* (really a leptomonad) in the larvæ, nymphs and imagines of *Culex fatigans*. This organism occurred in over 95 per cent. of the larvæ taken from a septic tank, and it is interesting to note that it was not found in two other insects (viz., *Culex concolor* and a species of *Joblotia*) breeding in the same water. These leptomonads measured 15 to 25 microns in length by 3 to 5 microns in width, while the flagellum was 25 to 40 microns. Rounded forms, almost globular in outline, about 4 microns long were numerous at the point of junction of the Malpighian tubes. It was eventually established that this was a natural flagellate of the insect.

Franchini (1911 and 1912) on feeding *Anopheles maculipennis* and *Stegomyia fasciata* on cultures of *Leishmania* from infantile kala-azar found flagellates (leptomonads) in the gut of the insects, but these may have been natural flagellates. Laveran and Franchini (1913) reported *Crithidia fasciculata* Léger, 1902 in *Anopheles maculipennis*.

Woodcock (1914) described and figured crithidial forms in hibernating *Culex pipiens* in London, and noted their resemblance to *Crithidia fasciculata* of Léger, but, in a further communication (1914), he considered these so-called crithidia as seen by himself and Novy, McNeal and Torrey, were not similar to Léger's *Crithidia fasciculata*, but were leptomonads. He therefore altered the name to *Leptomonas fasciculata* (*Crithidia fasciculata*) Novy, McNeal and Torrey, nec Léger). The same observer, while studying the parasites of the little owl, found leptomonad, crithidial and trypaniform flagellates in the gut of *Culex pipiens*, which had previously

J. G. Thomson, del.

Flagellates in *Anopheles umbrosus*.

been fed on an owl containing *Trypanosoma noctuæ* in its blood. These forms compare with those found by Schaudinn, but Woodcock was unable to attempt transmission experiments. Mathis in 1914 at Tonkin found the salivary glands of a *Culex* sp. heavily infected with the crithidial and trypaniform flagellates. The crithidia were 21 to 23 microns long with a flagellum 12 to 15 microns long, while the trypanosome forms measured 10 to 15 microns. Curiously enough, he could find no developmental forms in the gut, and he suggests that he may have been dealing with the trypanosome of a bird. Noller (1917) during the cultural experiments described leptomonads in *Culex pipiens*, which he identified as *Leptomonas fasciculata*, and in 1920 Laveran and Franchini found leptomonad, crithidial and trypanosome forms in *Culex pipiens*. Joyeux in 1918 recorded crithidial flagellates in *Anopheles maculipennis* from Macedonia, while Wenyon (1921), also from Macedonia, reported the same type in *Anopheles maculipennis* and *Anopheles superpictus*. Lastly, in 1914, Schulz described *Leptomonas fasciculata* in the gut of *Culex pipiens* and *Theobaldia annulata*.

Description of the Crithidial Flagellate Found in the Gut of *Anopheles umbrosus*.

The films available for study, which were from two female anophelines, were five in number. Three smears were from the gut contents, and two were from the salivary glands of one of the mosquitoes. These latter showed flagellates similar to those from the intestines, and, as the possibility of contamination from the gut during the dissection cannot be excluded, undue emphasis will not be laid on their discovery in this situation. For the purposes of description it is more convenient to differentiate the various forms of the organism into certain types, which, however, it must be remembered, are merely stages in what is probably a continuous life cycle.

(*a*) Leishmania-like forms. These were fairly numerous. In outline they were ovoid, measuring about 4 microns in the long and 2 microns in the short axis. The nucleus was placed towards one end, and had the parabasal body fairly near it. In the majority of individuals a well-defined rhizoplast could be perceived passing from the neighbourhood of the parabasal body towards the periphery (*Vide* fig. 1.)

(*b*) Small ovoid flagellates. The length of these oval or sometimes pear-shaped forms, exclusive of the free flagellum, varied from 3·5 to about 5 microns, and the width from 2 to 3 microns. The nucleus still had the tendency to be towards one end of the body, while the flagellum, which took origin from its neighbourhood, ran directly through the body to become free at the anterior end. The flagellum usually measured about the same length as the body. (*Vide* figs. 2, 3, 4 and 5.)

(*c*) Piriform flagellates. These were most commonly found in process of division. They were 10 microns in length by 4·5 microns in breadth. It seems probable that these piriform specimens are the precursors of the crithidial forms described below. (*Vide* fig. 6.)

(*d*) True crithidial forms. This type predominated in all the films. In size there was considerable variation, short, intermediate and long forms occurring. The shape of the body was characteristic, being elongated and pointed at both ends. The length was from 8 to 15 microns. The nucleus varied in position, being sometimes central (figs. 11 and 12), sometimes slightly anterior (fig. 13), and most frequently posterior (figs. 17, 18 and 19). The free part of the flagellum varied from about 2 to 5 microns in length.

DESCRIPTION OF FIGURES.

All figures were drawn at a magnification of approximately 2,200 diameters, and were specimens from one mosquito.

Fig. 1.—*Leishmania* forms.

Figs. 2, 3, 4.—Short ovoid forms, flagellates.

Fig. 5.—Short crithidial form.

Fig. 6.—Division of short, piriform flagellate.

Figs. 7, 8, 9 and 10.—Short, typical, crithidial forms with short free flagellum. The nucleus in fig. 9 is posterior in position.

Figs. 11, 12, 13, 14, 15 and 16.—Large crithidial forms.

Fig. 16.—Two crithidia occurring together showing the great variation in length.

Fig. 17.—Short crithidia with the nucleus situated in a posterior position suggesting the development of a trypanosome phase.

Figs. 18 and 19.—Thin crithidial forms with nucleus situated posteriorly.

NOTES BY A NURSE ON THE TREATMENT OF YAWS[1] (FRAMBŒSIA) WITH NOVARSAN.[2]

By FREDA WILSON.

(*Nursing Sister attached to the Universities Mission in Central Africa.*)

INTRODUCTORY REMARKS.

By J. B. CHRISTOPHERSON, C.B.E., M.D.

(*Medical Examiner to the Universities Mission to Central Africa. Late Sudan Medical Department.*)

APART from their intrinsic value the following notes are interesting for two reasons.

They clearly show that one of the prevailing serious African diseases is readily amenable to appropriate treatment and will probably be annihilated in course of time. This is well known already.

They incidentally demonstrate the quality of the work which is being carried out by mission nurses in Central Africa, particularly supervised by the medical officer attached to the mission.[3]

It must be kept in mind that Great Britain is successfully administering huge areas in the vast continent of Africa with a mere sprinkling of British officials, that pioneers and settlers are scattered sparsely throughout the land, and lastly, that Government doctors are few and private practitioners do not exist in many of the dependencies, and that the natives for the most part have only their own witch doctors to fall back on when ill. That if the nurses of the missions working in Central Africa did not treat cases of illness because they have not professional qualifications as doctors, much suffering which they now alleviate would be left to take its own dire course.

These 30,000 attendances at a small out-station dispensary were all voluntary, many of the natives attending walked miles for treatment—nothing but good resulted. The doses of the *novarsan* were all well within the bounds of orthodoxy.

It is true that the novarsan was given intravenously and that a great measure of discretion was called for, for people of all ages and illness of all degrees were treated.

The nurse is by no means the only nurse in Africa who is doing this class of work, and perhaps it is as well to add that the nurses of the Universities Mission to Central Africa who are called on to do

[1] *Yaws* is a disease confined to the tropics. In its clinical manifestations it closely resembles syphilis. It is caused by the *Spironema pertenuis* of Castellani which is not easily distinguishable from the *Spironema pallida* of Schaudinn of syphilis. It is not venereal but is contracted by simple contact with another case.

Travellers and writers after visiting African countries are apt to pronounce that the people are eaten up with syphilis or rotten with the same. They are wrong in making this stupid and immoral implication.

It would be truer to say that a large proportion of the natives in many parts of Africa were disabled by the easily curable disease called yaws, which is mistaken over and over again for syphilis.—J. B. C.

[2] *Novarsan* is a form of Novarsenobensol.

[3] By Dr. Mary Iles, M.D.(Lond.), and latterly by Dr. Janet Murray, M.D.(Edin.).

medical work of this quality belong to the grade from which the sisters in charge of wards at the London hospitals are drawn; several in fact have been sisters at London hospitals to which medical schools are attached.

Miss Wilson touches on points of professional interest in connection with her work: (1) Can yaws be congenitally transmitted? (2) Are the organic arsenical preparations alone capable of effecting a cure in secondary yaws? (3) What dosage of novarsan, and what after-treatment is necessary for tertiary yaws?

She goes far to prove that many of the chronic crippling intractable ulcers and contractures met with in Central Africa are due to *yaws* and are readily amenable to yaws treatment.

Lastly, there is the question, when can treatment be suspended in a yaws patient? A test is necessary. When Miss Wilson next goes out I hope she will be equipped with a test.

Yaws is not the only serious tropical disease the nurses of the U.M.C.A. treat in Africa: malaria, dysentery, ankylostomiasis, and, not least of all, leprosy, are all in the daily round.

WHEN I was sent to do work for the Universities Mission to Central Africa, at a mission station twenty miles inland above Targa, in Tanganyika territory, East Africa, I found a district which, to a newcomer to Africa, seemed to be a hot-bed of disease, mainly yaws and ankylostomiasis. The natives of the district belong to the Bondei tribe and are people of poor physique, and ignorant of the elementary rules of hygiene and public health; to the indigenous people is added a floating population of Africans from the interior who find work on the numerous sisal plantations; these visitors bring a great deal of disease with them.

The following statistics will show the urgent need there is for medical treatment in Central Africa, and the increasing use by the Africans of the medical help afforded by the Mission, the patients coming from an increasingly wide area:—

(*a*) *Year ending December*, 1923.

Attendances at Mkusi Dispensary (out-patients)	=	12,021
New yaws cases (secondary and tertiary)	=	1,100
New ankylostomiasis cases	=	450

(*b*) *Year ending December*, 1924.

Attendances at Mkusi Dispensary (out-patients)	=	21,114
Secondary yaws (new cases) ... ... 429 Tertiary ,, ,, ... 1,402	=	1,831
Ankylostomiasis	=	1,782

The routine treatment for *yaws* was intravenous injections of *novarsan*.

Total number of *novarsan* injections for two years = 4,500.

(I) SECONDARY YAWS.

The first year's injection work consisted mainly in curing the acute cases, of which the district was full; these for the most part came up covered with the rash and in a very infectious condition. During the second year's work these acute cases were in the minority, and now a case of secondary yaws with a rash is hardly to be found in the entire district.

Each paid a fee, either in money or kind, varying from one to five shillings, according to age; in this way this special branch of medical work was entirely self-supporting, and the receipts for injections paid by the Africans in the Mkusi district alone for January to December, 1924, amounted to £251. Psychologically this charge seemed to increase the value of the treatment to the African mind, as they are accustomed to pay heavily for what is done for them by the native witch doctors. In many cases, however, the injections were given practically free, the patients, when cured, bringing the money up months later; generally this was earned by working on the sisal plantations. No patient was ever refused treatment because of real inability to pay.

The treatment of secondary yaws was quite straightforward, and *in most cases* patients were cured by one or two injections. Adults of male sex were given 0·45 grm. and women 0·3 grm., though the dose varied according to the individual. Patients reported at regular intervals *for months after being "cured,"* and all were given mercury by mouth as routine treatment.

The following are two typical cases:—

(*a*) April 11, 1923. *Miniamisi*, aged 2, acute yaws. Breathing very laboured owing to nostrils being blocked with sores. 0·15 grm. novarsan given.

May 2, 1923. Cured. No recurrence since.

(*b*) October 10, 1923. *Mtoro*. Body covered with rash, walked up fifteen hours to dispensary. 0·45 grm. novarsan given.

October 14, 1923. Cured. Returned home. No recurrence since.

Several cases of children were brought up with no rash nor any outward sign, but complaints of pains in joints, mainly elbows and knees; in a few cases the children were quite crippled. Injection into the vein at the elbow was found to be difficult, as great pain was caused by straightening the arm out on the table, and in some cases there was considerable contraction. These cases were diagnosed by the natives as being *the very earliest stage of yaws*; they were certainly all cured by injection and, as far as I know, were not followed by the rash. Namely:—

January 2, 1924. *Mamtai*, aged 7, carried up on his father's shoulders. No sign of yaws. No past history of yaws. Pain in arms and legs. 0·2 grm. novarsan given.

January 16, 1924. Cured. Walked up. Has been quite well since.

Exceptions and Complications amongst Secondary Yaws.

(*A*) *Secondary Cases passing into Tertiary even with Treatment.*—Some isolated cases, although apparently responding equally quickly as did the average patient for whom no further treatment was necessary, remained quite free for some months, generally about four, and then either developed the painful tertiary form in their feet, or an obstinate form of ulceration responding to no local treatment. This perhaps points to a lengthier course of injection being given than has been thought necessary after the disappearance of the rash. Namely:—

(1) November 4, 1924. *Valentino*, body covered with rash. 0·45 grm. given.

November 18, 1924. Body quite clear. Patient apparently well.
March 3, 1925. Tertiary form in feet. 0·41 grm. given.
(2) October 15, 1924. *Binto Umari.* Body covered with rash. 0·3 grm. given.
October 25, 1924. Body clear.
December 10, 1924. Tertiary form in feet. 0·45 grm. given.
(3) June 28, 1924. *Akida*, child of 8, body covered with rash. 0·2 grm. given.
July 19, 1924. Body quite clear. Patient apparently well.
September 3, 1924. Ulceration on ankle not responding to any local treatment. 0·3 grm. given. Ulcer healed quickly. No recurrence.

(*B*) *Secondary with Recurrences.*—A few cases of secondary yaws were extraordinarily obstinate, apparently different from the usual type in virulence, and completely contradicting the preconceived idea that every case of yaws was going to be cured by one, or at most two injections of novarsan. Namely:—

September 10, 1923. *Ramathani*, history of acute yaws for six months. Body covered with rash. 0·45 grm. given.
September 20, 1923. Improvement, not clear. 0·45 grm. given.
September 26, 1923. Still not quite clear. 0·3 grm. given.
October 3, 1923. Rash disappeared. Patient apparently well.
February 18, 1924. Body covered with rash again. 0·6 grm. given.
April 16, 1924. Body covered with rash again. 0·6 grm. given. Not reported since.

It was interesting to note that in two cases of women treated for secondary yaws and, as far as outward signs went, cured, in the early months of pregnancy, the rash recurred in both cases immediately after the birth of the baby. In one case the breast became infected and the baby developed yaws apparently through being suckled; in the other case the baby remained free.

In the case of a baby of three months old brought up suffering from acute yaws, there was the history of the father being under treatment for yaws just at the time the mother became pregnant. This may have been merely a coincidence. The baby was cured by 0·1 grm.

(II) Tertiary Yaws.

(*A*) *Hands and Feet.*—The majority of the patients during the second year's work were those suffering from the tertiary form affecting the hands or feet, very painful and disabling. To effect a cure more of the drug was necessary than in the case of the rash, and these cases were very liable to recur at the rainy season. Namely:—

July 10, 1923. *Bendera*, history of yaws thirty years ago hands quite sore and useless—palms split. 0·3 grm. given.
August 7, 1923. Great improvement, beginning to use hands again, and able to pound the corn. 0·3 grm. given. Cured.

(*B*) *Ulceration.*—At first sight most of the dispensary work in Africa seemed to consist in the dressing of dirty offensive ulcers, in some cases most extensive and not responding at all quickly to local treatment, but dragging on for months. Little by little it transpired that the majority of these patients had a past history of yaws so novarsan injections were tried, with the result that from January to December, 1924, only one per cent. of cases of ulceration did not require injection. The other numerous cases of ulceration were injected and healed rapidly in a week or two, the dressing in such cases consisting generally of old rag dipped in saline, done by a great number of the patients in their own huts.

The alleviation of suffering throughout the entire district due to the rapid healing of these ulcers can hardly be appreciated enough, nor the gratitude of the natives.

The following are some of the cases:—

(1) September 5, 1923. *Halifa*, ill twelve years, brought up twenty miles in a stretcher. Right leg and genitals covered with ulceration. 0·45 grm. given. Daily dressing.
September 12, 1923. Ulcers healing rapidly. 0·3 grm. given.
October 3, 1923. Quite well, *walked* home.

Patient has been seen on several occasions, when he brought up relations for treatment, and is quite well.

(2) June 17, 1923. *Deburi*, aged 10, very painful ulceration of feet, spent days on road and arrived quite exhausted. 0·25 grm. given—stayed in neighbourhood for daily dressing. Rapid improvement.
July 20, 1923. Ulcers healed. Patient quite well, walked home, twenty-five miles.

(*C*) *Loss of Power in Limbs.*—Another class of patients, also giving a history of yaws in childhood, who responded so quickly to treatment by injection were those suffering from loss of power in their limbs. Whether this is a form of tertiary yaws or not remains to be proved.

The following cases give their own story:—

(1) September 4, 1923. *Omari*, ill twenty years, no use in lower limbs, brought up in stretcher, had to be carried into hut for injection. 0·3 grm. given.
September 18, 1923. Still carried up but able to help himself into hut. 0·45 grm. given.
October 2, 1923. Walked two and a half hours from his village to the dispensary.
Reported at intervals for one and a half years.
(2) February 28, 1925. *Ali*, young man brought up in stretcher—no use in legs, history of yaws as a boy, sudden loss of power fifteen months ago. 0·3 grm. given.
March 21, 1925. Improved—able to walk from entrance of injection hut to table with help on both sides. 0·3 grm. given.
April 18, 1925. Walked up from his own village, two and a half miles with two sticks. 0·3 grm. given.
Case still under treatment.
(3) September 26, 1924. *Michael.* Left elbow very swollen and painful. Foments applied, no relief, lot. plumbi also unavailing. 0·3 grm. given—arm put in sling.
October 14, 1924. Arm quite normal and in use. 0·3 grm. repeated.
Reported at intervals—no further trouble.

OBSERVATIONS ON CASTELLANI'S FERMENTATION PHENOMENON.

By Juan Manuel Fiallos, M.D.
From the Ross Institute, London.

Castellani has described the following phenomenon: when to a bacillus producing simple acidity, never gas, in a given carbohydrate—as, for instance, maltose—certain bacilli are added which are inert on that particular carbon compound, viz., do not produce in it either acidity or gas, fermentation with production of gas may take place. Accord-

ing to Castellani, a condition for the phenomenon to take place is that the added bacillus, though inert on that particular carbohydrate, must be capable of producing gas in glucose.

The phenomenon may be described in other words as follows: Simple acid fermentation of certain carbon compounds caused by certain bacilli which never produce gas, may be turned into fermentation with production of gas by merely adding a bacillus inert on those particular carbon compounds, but capable of producing gas-fermentation in glucose. One would expect, of course, that by adding to an organism producing, say in maltose, simple acidity, never gas, an organism which does not produce either acidity or gas in that sugar, there would still be only production of acidity.

I have repeated some of Castellani's experiments and I will give here my results.

Organisms Used.—The organisms used are *Bacillus typhosus*, *B. morgani* (Morgan's Bacillus No. 1), *B. dysenteriæ* Flexner, and a strain of *B. proteus*. As is well known, *B. typhosus* and *B. dysenteriæ* Flexner never produce gas in any sugar; *B. morgani* produces gas in glucose, levulose and galactose, it does not produce either acidity or gas in any other carbohydrate. The strain of *B. proteus* I have used (Strain P) produces gas in glucose, levulose, galactose, saccharose and glycerol; it produces neither acidity nor gas in lactose, dulcitol, mannitol, maltose, dextrin, adonite, inulin, sorbite, inositol, salicin, amygdalin, isodulcitol or erythrite.

B. typhosus + *B. morgani.*

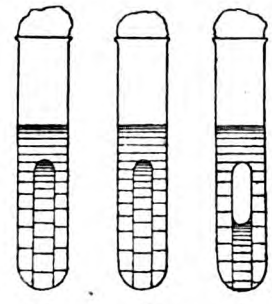
Action on Maltose.—*B. typhosus*, as is well known, produces acidity, never gas, in maltose; *B. morgani* produces neither acidity nor gas; the mixture *B. typhosus* + *B. morgani* produces acidity and gas.

Action on Sorbite.—*B. typhosus* alone produces simple acidity, never gas; *B. morgani* has no action whatever, it produces neither acidity nor gas; the mixture *B. typhosus* + *B. morgani* produces acidity and gas.

B. typhosus + *B. proteus.*

The strain of *B. proteus* used (P) as already stated has no action on maltose, mannitol or sorbite; it produces neither acidity nor gas in these substances.

Action on Mannitol.—*B. typhosus* produces acidity, never gas in this alcohol. *B. proteus* (P) has no action on it; neither acidity nor gas is produced. Their mixture, however, produces acidity and gas.



Action on Maltose.—*B. typhosus* alone produces acidity only, never gas; *B. proteus* (P) alone is inert, it produces neither acidity nor gas; their mixture produces acidity and gas.

Action on Sorbite.—*B. typhosus* produces acidity only; *B. proteus* produces neither acidity nor gas; their mixture causes production of acidity and gas.

B. dysenteriæ Flexner + *B. morgani.*

Action on Maltose.—*B. dysenteriæ* Flexner produces only acidity, never gas. *B. morgani* produces neither acidity nor gas; their mixture produces acidity and gas.

Action on Mannitol.—*B. dysenteriæ* Flexner produces acidity only, never gas. *B. morgani* has no action on it; neither acidity nor gas is produced. The mixture *B. dysenteriæ* + *B. morgani* produces acidity and gas.

1, Mannitol peptone water tube inoculated with *B. dysenteriæ* Flexner; gas absent. 2, Mannitol peptone water tube inoculated with *B. morgani*; gas absent. 3, Mannitol peptone water tube inoculated with *B. dysenteriæ* Flexner + *B. morgani*; gas present.

B. typhosus + *B. morgani* + *B. proteus.*

Action on Maltose, Mannitol and *Sorbite.*—*B. typhosus* alone produces neither acidity nor gas. *B. morgani* alone produces acidity, no gas. *B. morgani* *B. proteus* produces neither acidity nor gas. The mixture of the three germs produces acidity and gas.

Résumé and Conclusions.

My experiments confirm Castellani's work. The phenomenon he has described is the following: Two bacilli, neither of which causes production of gas in certain carbon compounds, may do so when artificially mixed together, provided one of them is capable of producing simple acidity (never gas) in those carbon compounds and the other, though inert on those carbon compounds (viz., does not produce in them either acidity or gas) is capable of producing gas in glucose.

For example, *Bacillus typhosus* never produces gas, only simple acidity in maltose, mannitol and sorbite; *B. morgani* alone is inert on those substances, viz., does not produce either acidity or gas; their mixture, however, produces gas, although one would expect that by adding to a germ which produces simple acidity, a germ which produces neither acidity nor gas, there would still be only production of simple acidity.

Similarly, neither *B. dysenteriæ* Flexner nor *B. proteus* (P) produces gas in mannitol; the first produces only simple acidity and the other is inert; their mixture, however, produces acidity and gas.

TABLE.

	Lactose	Saccharose	Glucose	Levulose	Maltose	Galactose	Mannito	Sorbite
B. typhosus	O	O	A	A	A	A	A	A
B. dysenteriæ Flexner	O	O	A	A	A	A	A	O
B. morgani	O	O	AG	AG	O	AG	O	O
B. proteus (P)	O	O	AG	AG	O	AG	O	O
B. typhosus + *B. morgani*	O	O	AG	AG	AG	AG	AG	AG
B. typhosus + *B. proteus*	O	O	AG	AG	AG	AG	AG	AG
B. dysenteriæ Flexner + *B. morgani*	O	O	AG	AG	AG	AG	AG	O
B. dysenteriæ Flexner + *B. proteus*	O	O	AG	AG	AG	AG	AG	O

O, negative, viz., neither acid nor gas produced.
A, acidity.
AG, acidity and gas.

ACQUIRED IMMUNITY TO MALARIAL INOCULATION.

By J. ERNEST NICOLE, L.M.S.S.A.Lond.,
Senior Assistant Medical Officer, Lancashire County Mental Hospital, Winwick,
AND
JOHN P. STEEL, M.B., Ch.B.Edin.,
Assistant Medical Officer to the Hospital.

IN connection with the malarial treatment of general paralysis of the insane in this hospital, we have endeavoured to produce a second series of malarial rigors in such cases as had not shown sufficient mental or physical benefit after a first infection terminated six or more months ago.

From the figures published from time to time by the originators of the treatment, we were led to believe that the inducement of a second series of malarial rigors was a matter of mere routine procedure. We were, however, surprised to find that such was far from being the case. Fourteen patients who were subjected to reinoculation, some even three times, showed no clinical signs of malaria.

To remove any possible doubt as to the technique of the inoculations we would say that we are aware that if only gametocytic forms of parasite were introduced no pyrexia could result. Proof that asexual forms were injected is to be found in the last column of the accompanying table, for in every case except one we can point to other patients who were inoculated from the same syringeful of the blood of the donor and who, later, developed true malaria, these patients being infected for the first time.

Having been confronted with such a definite im-

munity we had, perforce, to search for some factor peculiar to these immune cases which might be correlated with this resistance to subsequent infection, especially as we have found only one case to be resistent to a *first* infection.

In so far as naturally occurring malaria is terminated as speedily as possible by the exhibition of quinine, and whereas, in contrast, therapeutic malaria is allowed to continue to the limit of tolerance we thought perhaps the number of rigors in the primary attack was responsible for the subsequent immunity and that relapses might also be a factor.

Our figures show that such is not the case. Reference to our table will also prove that the inoculation methods of neither the primary infections nor the subsequent attempted infections had any bearing on the matter.

It should be added that all the primary pyrexias have been terminated in the usual way by means of quinine, which was administered until the blood was definitely negative to microscopic examination.

Further, our reinoculations have been performed at widely varying intervals of from six to twenty months.

In view of the theory advanced in support of the I.K. treatment of tuberculosis, viz., "that the more important protective substances of an immunized blood exist chiefly, though potentially, in the erythrocytes," we, for a time, thought that the relationship between the blood-groups to which the various donors belonged, and those of the recipients might prove a fruitful field for research. It seemed possible that the hæmolysis consequent upon the mixing of different bloods might thereby liberate certain antibodies capable of having been produced by the first malarial attack.

The inoculation would necessarily account for an extreme dilution of such liberated antibodies, as is laid stress upon by those who support the I.K. theory.

Although having no practical experience of I.K. therapy and no real knowledge thereof, it seemed worth while to investigate and type the blood-groups of the cases under review. We were again disappointed to find that no conclusion as to the significance of blood-grouping, in this connection, could be drawn, especially as all our donors except one happened to belong to group 4.

Owing to the difficulty hitherto experienced in obtaining infected mosquitoes we can, at present, point to but one case (No. 51) where a subsequent infection has been attempted by all three routes inclusive of mosquito bite. Colonel S. P. James, of the Ministry of Health, has recently arranged to assist us in this matter, so we hope it will be possible at a later date to report further on this point.

Whether the serum of an "immune" patient will abort or prevent the development of a rigour we are not in a position to say, nor have we the opportunity to ascertain, as the results obtained from the malarial treatment of general paralysis of the insane appear to be so beneficial, in our experience, as to prevent our terminating the pyrexia before we are compelled to by the condition of the patient.

In this connection it may be of interest to mention that where the necessary tests have been performed on the "immune" patients we have found that only two have failed to show some change in the cerebrospinal fluid (cf. also *Lancet*, October 31).

Our chief reason for publishing our findings is that the further research into such an acquired immunity, especially if carried out under more propitious conditions than those prevailing in a mental hospital, may yield results important to preventive medicine, and that it may be of use to others to know even such negative findings as it has been our lot to obtain.

Our best thanks are due to the medical superintendent, Dr. F. M. Rodgers, for permission to make use of our work for publication; to Professor Mackie, of Edinburgh University, and to Dr. J. G. Thomson, of the London School of Tropical Medicine, for much encouragement and kindly advice.

Aleukæmic Leukæmia with Multiple Skin Tumours (John Alexander Drake, M.D., M.R.C.P., *British Journal of Dermatology and Syphilis*, August-September, 1925).—The patient, a young man aged 25 years, came under observation with multiple skin tumours, resembling in appearance those associated with leukæmia. Microscopical examination showed that the tumours were composed of masses of lymphoid cells. Most of the superficial lymphatic glands were enlarged, as was also the glandular tissue of the mouth and throat. None of the deep glands were affected. Sections of the glands showed marked diminution of the "germ centres." The most striking change in the blood was a well-marked leucopænia, which, however, was associated with a relative increase of the lymphocytes (aleukæmia). The marrow was redder than normal, and much more cellular. There was evidence of erythroblastic proliferation, but the most marked feature was the increase in the number of lymphoid cells. During the period of development of the skin tumours (about six months) the health of the patient was apparently normal, except for fleeting pains in, and swelling of, the joints. Later the enlargement of the glandular tissue of the throat increased to such an extent that ulceration and obstruction to breathing were caused and tracheotomy became necessary. When the patient first came under observation (i.e., when the skin tumours were already developed) no enlargement of the liver or spleen could be detected. During the later stages the spleen became palpable and eventually both spleen and liver were markedly enlarged. Multiple areas of necrosis were found post mortem in most of the organs. These areas contained large diphtheroid bacilli. It is probable that these necrotic areas were of quite recent origin and were a terminal feature.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE TREATMENT OF YAWS.

IN view of the similarity between the causal organism of yaws, *Spirochæta pertenuis* of Castellani and that of syphilis, *Spirochæta pallida* of Schaudinn, it would appear probable that the known antisyphilitic medicaments would have similar, if not identical, action on both these organisms and on the diseases which they produce. Experience, however, shows that mercury appears to exert little therapeutic action as compared with its powerful effect in syphilis, whilst potassium iodide is fairly efficacious, and the same remark applies to tartarated antimony (tartar emetic). The most efficacious and rapid results are obtained from the organic preparations of arsenic such as salvarsan, first introduced in the treatment of the disease by Castellani, Strong and Nichols, or better still, its more recent, more soluble and less toxic derivatives, which have an almost magical curative effect on yaws in every stage of the malady. Novarsenobillon given intravenously in doses of 0·9 grm. for adults, 0·6 grm. for young adults, 0·3 grm. for children up to 10, and 0·1 grm. for children under 2 years of age, the symptoms rapidly disappear and relapses are uncommon. The average time in which a cure is effected is generally said to be about eleven days. Some authorities prefer to give several smaller doses than this. They recommend three to six intravenous injections of novarsenobillon at three to six days' interval. If one injection only is given 0·4 to 0·6 grm. should be the dose; when a course of three or more injections is carried out 0·3 grm. should be given at the first injection, 0·4 grm. at the second, and 0·6 grm. at the third and subsequent injections. It is considered that the systematic use of neosalvarsan in a community afflicted with yaws would, if adequately carried out, thoroughly eradicate the endemic disease. This method of prophylaxis should therefore be enforced in such a community together with other measures such as isolation and segregation, disinfection and protection of skin lesions or abrasions.

The patient should, when possible, be kept at complete rest in bed for several hours after the injection, and in patients with cardiac lesions the neosalvarsan injections should be preceded by a hypodermic injection of caffeine. Occasionally the patient may complain of headache after the injections, and there may be a rise of temperature, but very seldom are serious symptoms caused by the drug, though cases of transient coma, delirium, epileptiform crisis, nephritis and jaundice have been recorded.

In cases in which intravenous injections are not feasible, the novarsenobillon may be given intramuscularly in doses of 0·4 grm. dissolved in oil, deeply into the muscles of the buttock.

The success attendant on the recent introduction of bismuth preparations in the treatment of syphilis has led to the employment of these preparations in yaws. An oily suspension of sodium-potassium-bismuth tartrate, containing 64 per cent. of bismuth and known as Trépol, has been used for intramuscular injections. A more recent preparation, Neo-Trépol, consisting of precipitated bismuth in an isotonic medium, is said to be more active. It is given in the same manner and in the same dosage.

Two injections at weekly intervals have been followed by favourable results in both secondary and tertiary yaws. A soluble form of sodium-bismuth tartrate is preferred by some: 6 gr. dissolved in 3 c.c. of distilled water constituting a suitable dose for an adult and 1 gr. for babies.

Patients with neglected mouths are liable to develop stomatitis as a result of the bismuth method of treatment. To obtain the best results attempts to improve the general health should accompany or precede treatment either by neosalvarsan or by bismuth injections—such as good food, warm clothing, tonics, and occasional aperients, and during convalescence iron, arsenic and quinine are indicated.

Injections of tartarated antimony (tartar emetic), as given in sleeping sickness, appear to produce much less satisfactory results than those obtained with neosalvarsan or bismuth, and there would appear to be no reason for their continued employment.

When neosalvarsan or bismuth cannot be obtained or where lack of medical men and skilled nurses makes intramuscular injections difficult or impossible, the oral administration of "Castellani's yaws mixture" will be found effective in many cases. This mixture contains tartar emetic gr. i, potassium iodide 5i, sodium salicylate gr. x, bicarbonate of soda gr. xv, water or chloroform water to 1 oz. One ounce is given thrice daily diluted in three or four times the amount of water, to adults and youngsters of over fourteen years; half doses to children of eight to fourteen years of age, and one-third or less to younger children. To Europeans it is advisable to give half doses, as they do not stand full doses as well as do natives. The mixture is given in the doses mentioned for ten to fifteen days; it is then discontinued for about a week, and then given again for another ten to fifteen days. The results obtained by this method of treatment are very satisfactory in recent and fairly recent cases, and may be compared with those obtained by the salvarsan treatment. In chronic cases, however, the results are not so striking, and for these cases the treatment by neosalvarsan or bismuth, whenever possible, should be employed. F. E. T.

Annotations.

A Study of Methods of Disinfection of Eating Utensils in the U.S. Army (Major Starr A. Moulton, *Military Surgeon*, September, 1925).—The existing regulation in regard to the cleansing of eating utensils requires an excessive amount of heat for disinfection. This is difficult of accomplishment and necessitates the use of improvised and generally unsatisfactory equipment in most kitchens. Based upon the author's considerations, the following modifications of this regulation are recommended: Immersion of the eating utensils after thorough washing and rinsing in water at 75° C. for five minutes instead of boiling or steaming for ten minutes. The routine use of towels is not to be permitted except for the drying of metal equipment, such as knives, forks, spoons, &c. These, after thorough washing, rinsing and drying, should be placed in a hot oven for the completion of disinfection. This measure is recommended to eliminate tarnishing. To accomplish the proper disinfection of eating utensils when mechanical dish-washers are not available, the author is of the opinion that the use of live steam is most practical and convenient.

Studies on the Ætiology of Jagziekte. I. *The Primary Lesions* (E. V. Cowdry, *Journal of Experimental Medicine*, September 1, 1925).—Observations showed that the lungs of South African sheep, in a district in which jagziekte is appearing sporadically, differ from those of normal American sheep. Their structure is in general variable. They are more subject to the action of bacteria, demonstrable histologically, and to the effect of inhaled foreign material. The most significant difference, however, is found to centre in the interalveolar tissue, which in about 33 per cent. of the animals is definitely thickened beyond the range of variation in this direction observed in American sheep. The thickenings occur in localized areas several millimetres in diameter. They begin with engorgement of the alveolar capillaries and accumulation of macrophages and of lymphocytes. Many of the macrophages pass into the alveolar lumina and assume the appearance of typical epithelioid cells. These infiltrative and exudative changes are primary to the epithelial proliferations which always arise in tissues modified in this way and which it is proposed to describe in a second paper.

Studies on the Ætiology of Jagziekte. II. *Origin of the Epithelial Proliferation and the Subsequent Changes* (E. V. Cowdry, *Journal of Experimental Medicine*, September 1, 1925).—The epithelial proliferations, which are so typical of jagziekte, are chiefly of alveolar origin. They appear in areas of infiltration and exudation identical histologically with those occurring in sheep which are to all appearances normal, but which are derived from flocks in which the disease is endemic. They become very extensive and quite atypical in structure, but they never give rise to metastases, even to the adjacent lymph-glands. The primary infiltration of the interalveolar tissues continues and may lead to fibrosis and extensive consolidation, or leukocytes may accumulate in large numbers, penetrate into the alveoli and form areas of acute pneumonia. In fairly advanced cases of jagziekte it is common to find many stages of the reaction in one and the same lung. While it is possible that the disease may be due to a single and specific virus, and the epithelial lesions are certainly of a very special character, the pathological complex as a whole is such as might be caused by a variety of predisposing and exciting factors operating over a considerable period of time.

Goundou (Dr. J. N. Roy, *Revue de Laryngologie, d'Otologie et de Rhinologie*, January 31, 1925).—This malady is fairly frequent in natives of the Ivory Coast and the Gold Coast, but it has also been observed in nearly every other part of Africa. Cases have been met with in Asia, Oceania, Mexico, Brazil and the Antilles, and in all places no race is exempt from the disease. It is more frequent in males than in females, and appears in people of all ages. The true ætiology of goundou is unknown, although many theories on the subject have been put forth. When goundou is paranasal very grave complications affecting the eyes may set in; and when it is generalized, muscular and articular troubles are often present. As regards treatment, chirurgical methods are the only means of curing the tumours of the face; arsenicals, &c., have no curative action on the disease, but when it is generalized a cure is practically hopeless. Thirty-four cases of goundou are described in this paper.

Observations on Filariasis, Yaws and Intestinal Helminthic Infections in the Cook Islands, with Notes on the Breeding Habits of Stegomyia Pseudo-scutellaris (A. McKenzie, *Trans. Royal Society Tropical Medicine and Hygiene*, June 18, 1925).—In this paper some valuable statistical data are given of a hitherto uninvestigated portion of the Pacific. It deals chiefly with the islands of Rarotonga, Aitutaki, Mangaia, and Atiu. A geographical description is given of each of these islands. Disease due to *Filaria bancrofti* is general throughout the group, and is manifested in a variety of symptoms. The main filarial accidents that cause natives to seek treatment are abscesses, filarial fever (lymphangitis) or elephantiasis. The youngest case in which microfilariæ were found was 12 years old. The disease occurs more often in males than in females, and is less frequently found in native women of the better class who do not work in the fields, and live in the most luxurious types of houses. An attempt was made to discover all the varieties of mosquitoes present in Rarotonga. *Culex fatigans*, *Stegomyia fasciata* and *S. pseudo-scutellaris* were found in large numbers. Intestinal parasites are not rare in these islands; *Necator americanus* is the commonest. Carbon tetrachloride proved efficacious in the treatment of these affections. The author has treated 200 cases of yaws during the past twelve months. Both sexes are equally affected, and the age in which it most frequently occurred was between 4 to 8 years; there was also a large number of cases between 8 to 12 years and over 20 years. The position of the primary sore varied. Conclusions drawn from these cases are: The primary sore is of identical appearance with the secondary sore and occurs on a wound or ulcer. It rarely appears on a breach of skin surface that has healed aseptically. Although in American Samoa it is considered that affection is carried by flies, owing to the numbers of primary sores which appear on the face, especially on those places which are being constantly picked by children, the author considers that it is more often carried direct from patient to patient by the intervention of fingers. Secondary rash and desquamation have never been observed. None of the cases showed the initial fever and joint pains of the classical picture. Fifty-one cases presented lesions of the feet and no other active signs; these cases heal quickly under treatment with novarsenobillion. Sixteen cases of definite tertiary yaws have been seen.

The Incubation period of Benign Tertian Malaria (G. de M. Rudolf, *Annals of Tropical Medicine and Parasitology*, July 16, 1925).—The incubation period of the naturally-acquired benign tertian malaria is given by most authorities as being from six to twenty-one days, with, however, wide variations. In thirty-four cases inoculated by means of anopheline mosquitoes, the incubation period varied from seven to thirty days as measured by the first date on which parasites were found, and in thirty-seven cases from seven to twenty-five days as measured from the first rise of temperature. Subcutaneous inoculation of malarial blood gives, according to a number of writers, an incubation period of from one to thirty-two days. A series of fifty general paralytics inoculated subcutaneously with *Plasmodium vivax* showed that 90 per cent. gave a rise of temperature of from 101° F. to 102·9° F. in less than ten days. The first rise of temperature over 103° F. occurred within twenty-one days in 84 per cent. and within ten days in 38 per cent.

Following subcutaneous inoculation there is a well-marked correlation between the first rises of temperature to 101° F. and to 102° F. and the first finding of parasites in thin films. The frequency curves of the first finding of parasites in thick-films and of the first rise of temperature to 101° F. are very similar, although the observations were made upon two different series of cases inoculated with two different strains of parasite. Curves of the first finding of parasites in thin-films and the first rise of temperature to 103° F., in the same series of cases, are also somewhat similar. Intravenous inoculation of malarial blood gave an incubation period of from one to nineteen days in a series of sixty cases. In a series of twenty-eight cases, inoculated intramuscularly at Bexley and Winwick Mental Hospitals, the incubation period varied from six to twenty-three days. In ten series of cases injected subcutaneously with malarial blood it was found (*a*) that when similar numbers of parasites were injected the incubation periods were of somewhat similar lengths, and (*b*) that when different numbers of parasites were injected the incubation periods showed a marked tendency to be shortest when the dosage of parasites was the greatest. In one series of four cases this relationship did not hold as regards the first series of temperature, but only as regards the first dates on which parasites were found. In most series the length of the incubation period as measured by the first time that parasites were

found, under standard conditions, corresponded more nearly to the dosage than did the length of the period as measured by the first rises of temperature.

A New Medium for the Diffentiation of Bacillus coli in Water Analysis (J. L. Pawan, *Annals of Tropical Medicine and Parasitology*, September 30, 1925).—*B. coli* (lactose +, indol +) may be isolated by the standard method not only from fæces and polluted waters, but also from unpolluted soils and unpolluted waters. As a standard indicator of fæcal contamination its value is not, therefore, unquestionable. Local experience indicates that the utilization of citrate by *B. coli* may be of value in differentiating fæcal from non-fæcal *B. coli* in water analysis.

The Morphology of Mastigina Hylæ (Frenzel) *from the Intestine of the Tadpole* (Elery R. Becker, *Journal of Parasitology*, June, 1925).—*Mastigina hylæ*, an inhabitant of the posterior intestine of the tadpole, first reported from Argentine by Frenzel, shows the following characters: An amœba-like body and an amœboid type of movement. A nucleus at the extreme anterior end. A basal granule situated on the nuclear membrane, from which arises a short inactive flagellum, a rhizostyle, and a cape covering the anterior surface of the nucleus from which radiating threads are distributed to the periphery of the rounded anterior end of the cell. The structure of this protozoon may serve as a ground plan for the morphology of other entozoic flagellates, such as *Trichomonas*, *Chilomastix*, and even *Giardia*.

The Fallacy of the Test for Lactose Fermenters as an Indication of fæcal Pollution of Waters (Otto Schobl and Jose Ramirez, *Philippine Journal of Science*, July 1925).—The fallacy of the test for lactose fermenters as an indication of fæcal pollution is evident from the following conclusions:

1. Even though lactose fermenters other than true *B. coli* are frequently present in human and animal fæces, due to their wide distribution in nature and their presence in places where fæcal contamination is excluded, these bacteria as a group cannot be considered as an indication of fæcal contamination.

2. On the other hand, we are justified in considering true *B. coli* as an indicator of fæcal pollution owing to its relatively limited distribution outside of the human and the animal body.

3. True *B. coli* can be fairly readily differentiated from the other members of the coli group by the type of its colony on eosin-methylene-blue lactose-agar plate.

4. Comparative tests of *B. coli* strains failed to yield any criterion for the differentiation of *B. coli* of human origin from *B. coli* of animal origin.

5. Under natural conditions the pollution of water by *B. coli* originating from the fæces of water-living animals such as fishes, frogs and insects is not likely.

Malaria Infection as it occurs in Late Pregnancy; its Relationship to Labour and Early Infancy (D. B. Blacklock and R. M. Gordon, *Annals of Tropical Medicine and Parasitology*, September 30, 1925).—Malarial infection of the placenta is very common in native women in Sierra Leone; it occurs in about 36 per cent. of cases. Infections demonstrable in the peripheral blood are in comparison few, not only in parturient women, but also in non-parturient women, adult males, and even in children. The difference between the placental and peripheral incidence is in all probability due to a peripheral blood immunity. These intensely-infected women are practically negligible as a source of danger to the community, so far as gamete production and consequent anopheline infection are concerned. Pathological effects on the mother may be entirely lacking. The children may in some cases be born and survive, and may appear free from any effects. On the other hand, this series contains in other cases proof of a very complete association between maternal infection in the placenta and death of the child *in utero*, or within a seven-day observation period after birth. Examination of a large number of infected placentas showed that severe destruction of the erythrocytes may occur in the umbilical cord in spite of the absence of congenital malaria. The effects upon the child are explicable on the grounds that toxic substances are absorbed from the intensely-infected placenta of the mother, and that the accumulation of masses of infected red cells interferes seriously with the nutrition of the fœtus.

An Experimental Study on the Development of the Dwarf Tape-worm (Hymenolepis nana) (Yoshihisa Saheki, *Annals of Tropical Medicine and Parasitology*, September 30, 1925).—The six-hooked larvæ of the dwarf tape-worm about ten hours after ingestion penetrate the villi in the upper part of the small intestine and four days later become encysted larvæ (*Cysticercus*). Five days after ingestion well-developed larvæ emerge from their cysts and leave the villi. After seven days well-developed young dwarf tape-worms have some segments at the end of the body. After nine days their reproductive organs become visible. About fourteen days after ingestion the segments are full of eggs, in each of which can be seen a six-hooked larva (onchosphere). After about seventeen days the ripe eggs of the dwarf tape-worms are found in the fæces of the experimental animals. These experiments show that dwarf tape-worm eggs, which have been evacuated with the fæces of the host, are swallowed by animals or man with their food, and that the eggs hatch and the six-hooked larvæ are liberated in the small intestines, and later enter the villi of the small intestines, where they become encysted larvæ; then emerging from the cysts they grow into young dwarf tape-worms and upon maturity evacuate the ripe eggs. Therefore, without any intermediate host, the dwarf tape-worm can directly develop in the body of mice, rats, young monkeys, or man, especially children.

Stibosan ("*Von Heyden* '471'") (L. E. Napier).—Stibosan, the sodium salt of meta-chlor-para-acetyl-amino-phenyl stibinic acid, was first introduced for the treatment of kala-azar by the author at the Calcutta School of Tropical Medicine about two years ago, and the first report was published in December, 1923. Since then the compound has been used in a large number of cases, and its value has been confirmed, not only by the author, but by other observers. The drug is now obtainable in sealed ampoules containing either 0·2 or 0·3 gr. The required dose should be dissolved in sterile distilled water in order to make a 5 per cent. solution. The solution should *not* be boiled and should be prepared freshly. Comparatively strong adults can be given 0·2 gr. as initial dose and 0·3 gr. subsequently. More debilitated ones can be given 0·15 gr. initial dose and 0·25 subsequently; very debilitated patients should be given 0·05 gr., subsequent doses being increased cautiously. Children tolerate the preparation in relatively larger doses. Only two contra-indications are given to the use of stibosan in kala-azar, i.e., jaundice and ascitis. This preparation has many advantages over other preparations of antimony, one of the chief being that only about 12 injections are necessary to complete a cure instead of the usual 30 to 40 necessary with antimony tartrates. Various common sequelæ of intravenous injections of the tartrates are practically unknown when stibosan is used. It is also a stable substance, and does not undergo any change on exposure to air.

Izal in Cholera (Lalbehary Ganguly).—Izal has been given a fairly extensive trial in the Cholera Ward of the Campbell Hospital, and the results have not been as great as might have been expected. The author considers that izal, in the treatment of cholera, cannot be put on a higher level than any other drug so far tried. It is at a distinct disadvantage compared with others that have no irritant action on the kidneys. So far as any specific action is concerned, there is not much to choose between any of the drugs in common use *provided the drug exhibited has no irritant action on the kidney*. Success, of the standard of an 80 per cent. recovery amongst the pulseless cases, lies in judicious administration of salines and alkalies.

A Note on the Toxic Symptoms of Organic Arsenic (A. Denham White and R. Sahib Sital Chandra Dutt).—The authors call attention to the alarming sequelæ which may attend the treatment of syphilis by intravenous injections of arsenics; the danger lies chiefly in the fact that in the present state of knowledge there is no method of estimating the tolerance of any particular individual to the drug. Three cases are reported: In Case I nitritoid crises followed the administration of organic arsenic by injection, which ended fatally. The symptoms in Case II were similar to those in Case I, but the patient was removed from hospital and lost sight of. In Case III the patient developed jaundice after the injection and died shortly after. These symptoms may be averted by the use of adrenalin.

Soil Acidity and Survival of Hookworm Larvæ (A. C. Chandler).—It would appear from results obtained by experiments that the acidity likely to be present in ordinary agricultural soils, at least up to a hydrogen-ion concentration of 5·5, does not interfere with the survival of hookworm larvæ. This is contrary to the prevalent opinion that acidity in soil has a tendency to shorten the life of infective hookworm larvæ.

The Staphylococcal Kidney in Childhood (E. H. Vere Hodge).—In this paper the author calls attention to the danger of staphylococcal pyelitis and pyelonephritis of early childhood, in which there is direct evidence of the tonsil being the primary focus of infection. Four cases are reported which show the gravity of acute tonsillar affection in children. Some cases are accompanied by septicæmia, which progress rapidly to a fatal termination. In some cases there is marked acetone reaction in the urine in the early stages of the disease; although it is considered that this has no special significance, it should nevertheless not be neglected lest convulsions or coma should supervene.

Acute Inflammation of the Prostate (Henry Smith).—This disease is of more frequent occurrence than one is led to believe by the literature on the subject, and is very often misdiagnosed in surgical practice. The result of this is that the case is temporized with and allowed to declare itself by an abscess opening into the rectum or into the bladder. The general rule in cases which burst into the bladder or rectum is that they should be left to drain by that route without further interference. This, in the author's opinion, is quite wrong. When the abscess has burst into the bladder, the proper procedure is to pass a lithotomy staff and make a small lithotomy-sized wound and drain both bladder and abscess. In case it empties into the rectum, the sphincter should be freely incised and the front wall of the rectum right up to and into the abscess cavity. Another error which is pointed out is the general belief that gonorrhœa is the chief cause of this condition.

Reviews.

MANSON'S TROPICAL DISEASES. A MANUAL OF THE DISEASES OF WARM CLIMATES. Edited by P. H. Manson-Bahr, D.S.O., M.A., M.D., D.T.M. and H., F.R.C.P. Eighth Edition. With 20 Coloured Plates, 7 Half-Tone Plates, 387 Figures in the Text, 6 Maps and 33 Charts. 1925. Cassell and Co., London, New York, Toronto and Melbourne.

Manson's "Tropical Medicine" has long been a classic, and has now reached its eighth edition—the first to appear since the death of its original author.

Sir Patrick Manson. The editor, Dr. P. H. Manson-Bahr, has thoroughly succeeded in his endeavour to bring it abreast of the latest development of this branch of medicine. To do this the volume has been drastically revised, and indeed remodelled, the only portion of the work as it came from the pen of Sir Patrick Manson and retained for its historical interest is the introduction of twenty pages on the Etiology of Tropical Diseases. Not the least important part of the book is the appendix of 232 pages, comprising Section A—Medical Zoology; and Section B—Laboratory Methods. The former comprising medical protozoology, helminthology, entomology and herpetology has been entirely rewritten, many new illustrations having been introduced. Fresh illustrations have also been inserted in other sections, ninety-four being new to this edition, including four full-page plates. The editor is to be congratulated in keeping down the size of the volume, for, in spite of the large quantity of new matter for which room has been found, he has succeeded in making this edition shorter than the last by some seventy pages. By the appearance of this excellent edition the continued popularity of Manson's Tropical Medicine is assured.

Fifty Years of Medical Progress (1873-1922). By H. Drinkwater, M.D. Published by H. K. Lewis and Co., London. Price 10s. 6d.

The subjects are treated in alphabetical order. Under the heading "Anthrax" mention is made of Koch and Pasteur. The latter already in 1857 had made the startling assertion that fermentation is due to organic life. Mainly through his efforts vaccination against anthrax was successfully introduced. Several pages are devoted to the anatomy of the brain, brain surgery having of late years made great strides. In the 70's Joseph Lister, professor of clinical surgery, was waging his heroic war against wound sepsis. People sneered at him and called his ideas fads; Koch, however, supported him and in a book on "Wound Infection" made his ideas known in Germany; now sterilizing is universally practised.

In the pages dealing with drugs and their discoveries, attention is drawn to the valuable work done in this respect by Emil Fischer, of Berlin. Notice is drawn to the great progress made in "Embryology" in late years. The article on "Eugenics" is interesting, but the unemployment problem is not in any way solved by the oft-repeated assertion that the unemployed are too often unemployable. In the section on "Germs" a rapid enumeration is made of all contagious diseases, and the discoveries made regarding leprosy, dysentery, typhoid, kala-azar, yaws, &c.

Much attention has been given to the "Heart" during the past half century, and important discoveries in its anatomy and physiology are recorded. A list is given of the most important works on medicine and surgery which have appeared during the period under review. "Immunity" is very fully treated and blood transfusion is dealt with in the same section. Mention, too, is made of "Malaria" and the noble work of Ross, Manson, Celli and others in their efforts to discover the cause of this strange disease and to stamp it out. Many ideas on the nervous system and its diseases have been modified of late years and the war has thrown new light on many points that were hitherto obscure. *Sanitation* and *Sanatoria* come in for due notice and allusion is made to the different Factory Acts.

Under the heading "Surgery" mention is made of *Bone-grafting*, which, though so widely used during the war was practically unknown until the present century. Sir Arbuthnot Lane's method in the treatment of fractures, or rather preventive measures, is one of the most striking innovations of the past half-century. These are stray gleanings from the rich harvest of experience gathered together in the book. It has some good photographs of many distinguished medical men and a useful index. The paper, printing and binding are all of the excellent quality we have learned to expect from the firm of Lewis and Co. The compiler, Dr. Drinkwater, has prefaced the book with an outspoken foreword. He is evidently a man who says what he thinks and means what he says.

Artificial Sunlight and its Therapeutic Uses. Second Edition. By Francis Howard Humphris, M. D. (Brux.), F. R. C. P. (Edin.), D.M.R.E. (Cantab.), 1925. Oxford Medical Publications.

The value of heliotherapy or the use of the actinic rays of the sun in the treatment of disease has been long recognized, but the use of artificial sunlight for this purpose, due to the ultra-violet rays contained therein, is of quite recent growth, and is quite parallel to the growth of other branches of therapeutics, for, as Rollier points out, "Sun and ultra-violet rays bear much the same relation to one another as crude drugs do to their synthetically prepared chemical substitutes." In this volume Dr. Humphris has excellently succeeded in his attempt to put in handy and simple language the main conclusions that have been arrived at, experimentally and clinically, by authoritative research workers and to embody some of the more important results with ultra-violet radiation attained in his own practice. It will be found a safe guide to practitioners in a comparatively little known region of physical therapeutics. After chapters on the ultra-violet rays historically considered and on ultra-violet rays—facts and fallacies—comes an excellent description of the apparatus employed, namely, mercury vapour lamps, both air cooled and water cooled, and arc lamps of carbon, tungsten, or iron, or a mixture of these and certain other elements. The therapeutics of ultra-violet rays and technique of treatment are then described. A long array of diseases for which ultra-violet rays are employed, including as specially amenable tuberculosis, rickets and many skin diseases. The tropical diseases for

which this treatment is mentioned as applicable are sprue and Leishman's sore. X-ray as a complement to actinotherapy provides the last chapter, and a sufficient bibliography and good index complete the volume.

LEPROSY. By Sir Leonard Rogers and Ernest Muir. 12s. 6d. Published by John Wright & Sons, Ltd., Bristol, and Simpkin, Marshall, Hamilton, Kent & Co., Ltd., London.

This book refutes the oft-repeated saying that leprosy was unknown in Europe until it was brought back from the East by the Crusaders, for in it we are told that Pompey's soldiers brought it to Italy B.C., and it was known in Germany in the second century. In the eighth century Pepin, King of France, passed a law making marriage with a leper illegal and the disease a sufficient cause of divorce for those already in wedlock. It was introduced into the New World by the African slaves that the Spaniards brought over to work in the mines and on the plantations. It appears to be more common among men than among women. The disease is not hereditary, as had long been supposed. Children of leper parents, if taken from them shortly after birth, grow up healthy and have healthy offspring. The disease is caused by the bacillus of Hansen discovered in 1872. No other organism has ever resisted the efforts of bacteriologists so long. It has never yet been cultivated *in vitro*, or outside of the human body. Inoculations into guinea-pigs, rats and mice have proved negative. It is very contagious, though the mode of infection is not yet known to a certainty. Probably the bacillus enters the organism through skin abrasions or through the mucous membrane. Among bare-footed races the lower extremities are generally found to be the first parts affected. The conditions favourable for propagation are a hot moist climate, low condition of civilization, bad sanitary arrangements and poor food. The number of cases found in Norway, where much fish is eaten, caused Sir Jonathan Hutchinson to name it "Fish-eaters' gout," but this can hardly be considered conclusive, as it is almost unknown in Greenland, where fish is also the staple food. No age is quite exempt, but the most susceptible periods seem to be from five years of age upwards till puberty; the liability to contract the disease diminishes after 30. If treated medically from the onset it is probable that the disease would never reach the stage at which it becomes contagious, but the long incubation period (average 3½ years) makes its early treatment difficult; ignorance and fear are the chief obstacles that the doctor meets with in his fight against this fell plague. The arguments for and against segregation and isolation are dealt with exhaustively in the book, and charts and diagrams show the results obtained under different conditions of treatment.

The book is divided into sections. It contains many illustrations showing the disease at different stages of development or treatment. No absolutely efficacious remedy has yet been found, but the malady is no longer considered as hopeless. Oils, ointments, caustics, injections subcutaneous and intravenous, have all been found beneficial, and the manner of administration and comparative charts showing results already obtained make the book more helpful to the physician who for the first time finds himself faced with the leprous patient. A thing that often makes early treatment difficult is that leprosy has symptoms that are common to many other diseases. A whole chapter is given to this subject; the book also contains minute directions for bacteriological examination of patients, and so that the practitioner may not forget the rules of ordinary prudence, cases are cited of doctors who have infected themselves while examining or operating upon leprous patients.

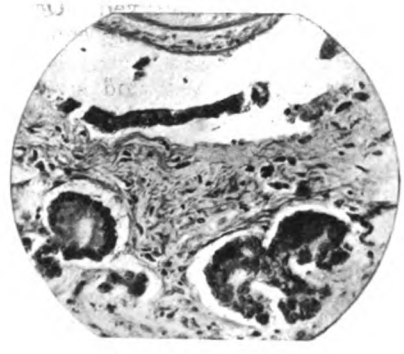
The Indian Lepers' Act, as amended up to 1920, is given as an appendix, also the official text of the resolutions of the International Conference on Leprosy assembled in 1923; the latter in French. A good alphabetical index at the end of the book will be found very useful by the busy doctor. The book is perfectly up to date, having been published in the first month of the present year. Paper and binding are fairly good and the printing clear. The numerous charts and diagrams show that most minute and conscientious attention has been given to the subject.

The authors are to be congratulated on the success of their labour.

SWANZY'S HANDBOOK OF DISEASES OF THE EYE. 13th edition. By Louis Werner, M.B., F.R.C.S.I. Published by H. K. Lewis & Co., Ltd., London. Pp. xvi + 698, with illustrations including coloured plates. Demy 8vo. Price 21s. net.

The thirteenth edition of Swanzy's "Diseases of the Eye" has now appeared under the able editorship of Mr. Louis Werner, who has done his work well. The present edition has been completely and carefully revised, especially in connection with diseases of the iris, of the ciliary body, and of the chorioid, the accounts of which have been, in part, rewritten. Notwithstanding this, and the addition of a few illustrations, as well as many minor alterations and additions, the volume has only been increased in size by some twenty-odd pages. It thus retains its well-known characters. The student and practitioner will find a sound and reliable guide to the subject of ophthalmology in this handbook, and we have no hesitation in warmly recommending it to his notice.

New Preparations, Inventions, &c.



SULFOXYL SALVARSAN.—This preparation has recently been issued by Messrs. Meister, Lucius and Brüning, of Hoechst, in a 5 per cent. solution ready for immediate use. Sulfoxyl Salvarsan is chiefly used in the treatment of tertiary syphilis, and is now being employed by a number of hospitals and V.D. centres in this country.

To illustrate "The Pathology of *Clonorchis* Infection of the Pancreas," by H. B. NEWHAM, C.M.G., M.D., F.R.C.P.

Original Communications.

THE PATHOLOGY OF *CLONORCHIS* INFECTION OF THE PANCREAS.

By H. B. Newham, C.M.G., M.D., M.R.C.P., &c.
Department of Tropical Pathology, London School of Hygiene and Tropical Medicine.

Clonorchis sinensis is a parasite which, when infesting man, is commonly found in the liver, living in the bile-ducts of that organ. This condition is well known, and the pathological lesions associated with the presence of the parasites in that organ have been studied and described by several authors.

The fact that these parasites may also, on occasion, be found infesting the pancreas has also been noted. Thus in Byam and Archibald's [1] "Practice of Medicine in the Tropics" it is stated with regard to these flukes, "In heavy infestations a few are found in the pancreatic ducts and duodenum." Again, Manson-Bahr [2], in Manson's "Tropical Diseases," says, "Some instances are recorded of the presence of this trematode in the pancreatic ducts, in the duodenum, and in the stomach, and of the complication of ascites and even of anasarca." Brumpt [3] also states that when the infestation is intense the pancreas is generally invaded and altered.

It would appear, therefore, that although the liver is the organ *par excellence* to be invaded by these parasites, it is only occasionally that the pancreas also is involved, and then only where the infestation is a massive one.

I have recently had the opportunity of examining pancreatic tissue invaded by these parasites. The history of the origin of the tissue is unknown, as it was found among the stock of pathological material belonging to the Department of Tropical Pathology of the London School of Hygiene and Tropical Medicine, and, unfortunately, no particulars of its origin, or of the case from which it was obtained, were available.

In examining this tissue with the naked eye, one was at once struck with the large size of the ducts, in which in several places parasites could be seen in the lumens. To the feel, the tissue seemed somewhat hard and tough, as if due to fibrotic thickening. Sections of the tissue were prepared and stained by various methods for a detailed examination of the pathological changes.

It is generally stated that the pathological changes produced by these parasites in the pancreas are similar to those produced by the same parasite in the liver, but investigation showed that in several respects the changes noted differed notably from those seen in the latter organ, of which a large number of sections were examined for purposes of comparison.

On microscopic examination of the pancreatic sections the most conspicuous change was the marked enlargement and thickening of the pancreatic ducts.

This thickening was due to a marked increase of the fibrous tissue which was dense and well-organized. Embedded in this fibrous tissue were a number of secondary, generally incomplete ducts. (fig. 3). These ducts, lined by a single layer of columnar epithelium, appeared to be an attempt by the organ to form subsidiary ducts to relieve the main duct, markedly blocked as it is by the parasites.

The parenchymatous cells of the organ abutting on these thickened ducts are somewhat atrophied, apparently from pressure, and, in some cases, show fatty degeneration. No definite changes could be made out in the islands of Langerhans, but the whole organ appeared to show some increase in the amount of fibrosis, constituting a mild form of cirrhosis.

Epithelial Changes.

The normal lining of a pancreatic duct is a single layer of columnar epithelium (fig. 1). In the ducts inhabited by *Clonorchis* this epithelium is almost invariably destroyed. Occasionally, some remains of this cellular lining can still be observed, (fig. 2), but, in such a case, the individual cells are considerably altered, and somewhat atrophied.

Later, in some of the affected ducts a new epithelial lining may be developed. This lining consists of cells of a different type, being of a squamous, flattened variety. These cells form a definite layer, many cells thick (fig. 5), the whole resting on a delicate substratum of fibrous tissue, which would appear to be separate from, but resting on, the dense fibrous tissue of the wall of the duct. This thickened epithelial lining appears, in some instances, to be actually superimposed on the remains of the old columnar cell layer, and in such instances one can see a very definite layer of these heaped-up squamous cells resting on a delicate base of fibrous tissue, and overlaying the somewhat atrophied cells (fig. 6).

It is difficult to conjecture how this squamous-celled lining comes to be formed, as it does not appear to show any definite origin from the underlying tissue.

In rare instances, this heaped-up stratum of squamous cells may actually project into the lumen of the duct as a definite papillomatous-like growth (fig. 4), and such an appearance suggests the possibility of the latter taking on malignant characters.

It may well be that in the accounts of the later stages of clonorchiasis, in which it is stated the patient may suffer from recurring jaundice, ascites, general emaciation, and cachexia, such symptoms may be in keeping with an ultimate malignant condition.

This peculiar epithelial hypertrophy is not, in my experience, seen in the liver, and would appear to be peculiar to pancreatic infections. The underlying causes of these marked changes in the tissue of the pancreas are a matter of conjecture. Seeing that the ducts in many cases are practically completely occluded by a mass of the

parasites in the lumen, this mechanical blocking would appear to act as the stimulating agent in inducing the organism to endeavour to form new subsidiary ducts in the thickened wall of the main duct (fig. 3), in order to allow the secretion of the gland to find a channel for its exit.

The peculiar epithelial changes described are difficult to account for. Possibly the presence of large numbers of the parasites in the ducts may produce a definite irritative effect.

On the other hand, the parasites may produce some irritative toxic substance, which, escaping into the lumen of the duct surrounding the parasite, may be responsible in great measure for the abnormal cellular proliferation.

ON THE MODIFICATION PRODUCED BY RADIUM ON AN EMULSION OF AN ADENO-CARCINOMA OF THE MOUSE AND ITS TRANSFORMATION INTO A CURATIVE VACCINE.

By Prof. G. Tizzoni,
The Royal University of Bologna,
Prof. E. Cetanni,
The Royal University of Modena,
and
G. de Angelis,
Professor of General Pathology.

In the most intense advance of the study of malignant tumours, we think it opportune to state in the present note how much we have been able to observe in experiments, which, even if preliminary, have at least been precise and repeated, concerning the action of radium on adeno-carcinoma of the mouse, and offer, as far as we go, the basis of a work of most ample growth, which involves a boundless succession of practical and scientific questions.

The specific cure of tumours, notwithstanding the many ways which have received extensive trial, does not yet allow a light to arise on the horizon. A brighter ray seems now to have arisen in the recent announcement of Gye and Barnard; but a critical examination of this research, although shedding a little light on the nature of the filtrable virus of chicken sarcoma, in no way illuminates the genesis of tumours common to the mammalia, and above all nothing appears from these studies towards solution of the problem of cure.

As the source of material therapeutic for the affections produced by a virus, there always remains the efficiency of the ancient principle that that which among the pathological products is of direct value is produced during the growth of the virus itself as being chiefly suited beneficially to influence the course of the disease which is derived from it, and is that which can still, at the present day, inspire the greatest faith in the study of cancer and other malignant tumours.

To ensure a profitable result it is not absolutely necessary that the nature of the virus be known; in many diseases, in fact, there is a filtrable virus, as in rabies, variola, infantile paralysis, encephalitis lethargica and many others, and the principal scientific and practical problems in reference to these were studied by the investigation of the pathological products directly obtained, though ignoring the morphological characters of the virus and the possibilities of culturing it artificially.

In these cases the essential solution of the problem consists in finding in these products, which contain the virus in natural culture, the certain conditions which determine the fatal limit of the death of the virus without at the same time causing damage to its vaccinating properties.

This problem is precisely that with which the present research is concerned, taking for its subject adeno-carcinoma of the mouse and for its destructive agent radium, with its known potentialities on tumours, and the possibility of guarding against its effects.

For such studies, for which we feel that our previous researches have fitted us, we have necessarily invited the resources of our respective institutes, thereby supplementing the deficiencies as a special centre for the study of cancer which our own district unfortunately possesses.

We have thus made use of the amount of radium possessed by the Institute of General Pathology in Bologna, and for the tumour an adeno-carcinoma transplanted through a long period and preserved at its full virulence in the Institute of General Pathology in Modena.

The dose of radium consisted of 0·10 grm. of pure bromide of radium, safely enclosed in a little box of the English type, with a potency of 500,000 U.R. per centigramme and a total of 5,000,000.

The tumour with which we worked is famous for its study by Ehrlich and later by many other authors. Suffice it to say that it presents the classical histological findings of mammary adeno-carcinoma, that with grafts beneath the dorsal skin in mice, after an incubation period, which, in cases of the greatest virulence, lasted exactly five to six days, but which, on the average, was about ten to twelve days, constantly produced granules of pure neoplasm nodular and characteristically lobed with unlimited power of increasing in size and which always attain considerable dimensions until at last it reaches a mass equal to, and sometimes beyond, that of the animal bearing it, and finally terminates by becoming ulcerated and determining the death of the mouse.

The attachment of the graft succeeds in 100 per cent. of the experiments, only in the rarest cases, and then only in old animals or during pregnancy

and lactation, the graft may end in total failure, although in this case there is an initial growth, but this is followed by complete re-absorption.

As regards the technique employed in this research, we have adopted that already used in the same institute in Bologna in the investigation of the action of radium on the virus of rabies and on that of variola vaccine.

Researches on the action of radiation, by Roentgen rays and by radium, made on tumours *in vivo*, which are very numerous, are of no value in our problem. It is admitted that the tumour can be destroyed by two quite distinct mechanisms, either directly by the action of radiation on the neoplastic cells, or indirectly by the action of atrophy-producing substances which are obtained from neoplastic material when subjected to the working of radiation. This double action cannot be differentiated during radiation *in vivo*. In this case, however, some indication of this indirect factor can be deduced by comparison with its more frequently observed retrogressive action on metastases at a distance from the radiated points. This indirect action of radiation is now admitted, by which radiation excites the production of inhibitory principles in the tumour and produces their action by way of the general circulation.

The study of our problem was conducted upon emulsions made with isolated tumours. Researches by this method have been made tentatively, but not in sufficient numbers and without having led to concordant and definite conclusions. The most regardful agree with those of Wedd and of Chambers, Morton and Russ, who found that the cells of tumours radiated *in vitro* are in a special condition to confer a state of immunity, but that if the radiation is too protracted the immunity sinks to zero. The most active rays appear to be the β, whilst the γ possess only slight action; Haarland, however, does not confirm these results.

Our researches may be arranged in three series, to which we refer successively:—

(1) Modifications produced by Radium on the Pathogenic Power of Cancerous Emulsion.

In this first series we proposed in the first place to see if and what action radium exercised on cancerous emulsion when in contact with half the usual amount of aluminium, and in the affirmative case we wished to establish what is the time which this contact ought to be maintained, so that decomposition should result until complete annulment of pathogenic power as ascertained by grafting into mice.

In order to avoid the influence of the surrounding temperature on the activity of the cancerous emulsion, as well as on the substance exposed to the action of the radium, as much as that of the control being kept up to the moment of grafting in an ice-chest at a temperature of not more than 4° to 5°.

In this first series of experiments we very easily succeeded in establishing the extreme limit of the scale of decomposition determined by radium on cancerous emulsions.

In fact, after 2½, 5 and 10 hours radiation the grafts of the radiated cancerous emulsion constantly gave positive results, determining the growth of a tumour which, whether judged by the brevity of the period of incubation or by its course and results, could in no way be distinguished from that obtained with the control grafts of the same emulsion, but not radiated.

Hence from these results we are able to affirm that by our dose of radium at ten hours exposure to radiation the cancerous emulsion preserves its pathogenic power intact.

Equally easy was it to find the upper limit. When the exposure of the cancer-emulsion to radium was prolonged to forty hours it was successful in every case, being indifferent as to when it was injected into the mouse, and this even if the observation of the animal into which the graft had been made was continued for many months. Indeed, the controls operated on with half of the emulsion not exposed to radium, but maintained in conditions identical to those of the radiated, constantly presented tumour growth without any modification as to whether the grafts had been practised from animal to animal with fresh emulsion.

From this we have been authorized to conclude that forty hours exposure to radium of our dose constantly and definitely annulled the pathogenic power of the cancerous emulsion of the adenocarcinoma of Ehrlich.

If, perchance, it is thus possible easily and successfully to establish the extreme grades of action of radium upon cancerous emulsions in regard to the time of radiation, it is not otherwise easy to obtain with absolute precision the intermediate grades, which, for us, present the greatest interest.

In this respect we have now been able to demonstrate that twenty hours radiation has represented the uncertain fatal limit, and that twenty-four hours radiation has constituted the fatal limit somewhat lower, according to the present finding.

In fact, in three animals operated on with emulsion exposed for twenty hours the result was not less sure and constant, although with diminished effect; of these two only succeeded positively, but with much retarded growth of the tumour, after thirty-five and sixty-one days respectively, and with a course somewhat slower than usual, though the result was always lethal. In animal No. 3 the result remained permanently negative. Indeed, after twenty-four hours' radiation the effects were constant, that is, no positive grafts in the mice treated with emulsion for this period of time.

From this it may be concluded that twenty hours radiation are not yet sufficient completely to annul the pathogenic power of cancerous emulsion and that the minimum time in which to obtain this effect as revealed by us is twenty-four hours. There still remains a restricted space

of four hours time to be explored to reveal it and how it behaves in the two times presently found; that is, we propose to undertake further research, precisely directed to filling up this gap. So far, according to the actual state of the matter, we can present this scale:

After 10 hours radiation ... No demonstrable action
„ 20 „ „ ... Incomplete and inconstant action
„ 24 „ „ ... Complete and constant action

In the presence of these results one most important consideration has not escaped notice: the analogy which the behaviour of cancerous material in the presence of radium reveals with other diseases undoubtedly due to filtrable viruses, such as rabies, Jennerian vaccinia, &c.

(2) Beneficial Effects produced by Properly Radiated Cancerous Emulsion on the Course of Developed Cancer.

In order to determine better the numerical limit of inactivation of the radiated cancerous emulsion in so far we wished to see if, like emulsions completely deprived of their pathogenic action, they had curative properties like that submitted to twenty-four hours of radiation, as this should be very near to the real fatal limit.

The results obtained in this series of experiments are as successful as they are encouraging. We have, indeed, observed that the injection of 2½ c.c. of the emulsion radiated for twenty-four hours made into the tumour which had already visibly grown and had reached considerable dimensions (maximum diameter 20 to 25 mm.) arrested the growth of it and brought about its gradual recession until it had completely disappeared. This involution of the neoplasm is accompanied by a peculiar softening of the tumour which becomes pulpy and little by little disappears without leading to ulceration and without producing any lesion whatever in the overlying skin. Later researches will describe what are the histological modifications which accompany the reabsorption of the tumour and complete cure.

Only exceptionally, when to the injection of the emulsion there is added some external mechanical cause, even merely the pressure exerted by the collodion applied to protect the part, there may be observed a dry aseptic necrosis of the tumour, at first partial and then extending to the whole of the neoplasm, which cleanly separates from the surrounding normal tissues by a limiting sulcus. It is ultimately cast off, leaving the impression of its contour which forms a sort of sac beneath the tumour, a process of repair and regeneration of the skin and sometimes some fine hairs. Instead, if in the cure of the tumour cancerous emulsion radiated for forty hours by the method indicated was used, success was quite indifferent, and the neoplasm followed its course to a lethal issue, without any appreciable difference from the controls. Therefore, between the fatal limit with conservation of the curative vaccinating power and that a little more elevated at which the vaccinating property also disappears, there intervenes by how much is now known, a long period of time, which in our experiments was found to be sixteen hours.

With this then we have established that the emulsion radiated for twenty-four hours, although it has completely lost its pathogenic power, has yet preserved a good part of its vaccinating powers, so that it acts most effectively on the same tumour as that from which the emulsion was derived, determining its complete disappearance, having acted as a curative auto-vaccine.

None can avoid the importance of this conclusion in that the proper grade of radiation can make the vaccinal effects comparable to the proper attenuation of a virus or of the respective cultures first revealed by the immortal genius of Pasteur in the transformation of the virus of vaccinia.

(3) Mechanism of Action of Properly Radiated Cancerous Emulsion in the Cure of Cancer.

After having recognized the curative action of cancerous emulsion the need spontaneously arose of knowing by what mechanism this action is exercised. And more precisely if this beneficial effect can be ascribed to the category of direct action, whether, that is to say, it should be related to the induced radio-activity conferred by the radium and afterwards to the emanations and radiations which the radiated emulsion has liberated in the heart of the tissues into which it was injected during the period of disactivation; or whether it should be ascribed to the category of indirect action, whereby the effect of the vaccinating principle developed in the emulsion under the influence of radiation.

To this end we have activated a solution of an indifferent salt, choosing physiological solution of sodium chloride and exposing it to radium for the time necessary to leave a clear impression on a photographic plate, equal in intensity to that left by the cancerous emulsion under identical conditions.

The radiated saline solution was then injected in the amount of ½ c.c. round a tumour already arrived at various periods of growth without producing in the neoplasm any modification in its development, course or issue. The death of the animal supervened in the same time as that of the control. Equally negative results were obtained with cancerous emulsion kept in the ice-chest for twenty-four to forty hours, but without being exposed to the action of radium.

It still remained to be seen whether an emulsion of physiological origin conveniently radiated had the same effect as the cancerous emulsion on tumours heavily developed; we observed that the mouse exhibited much sensitiveness to the toxicity of the degeneration products of heterogeneous tissues.

The completely negative effect of the control permits of the conclusion that it is not to the induced radio-activity acquired by the cancerous emulsion by the effect of its exposure to radium and not merely to the preservation of this emulsion in the cold for a time equal to or greater than that which serves to confer the vaccino-curative power on the

radiated emulsion, to which the efficacy of this last is due, as if the same constituents of the cancer which are found in the relative emulsion and to its transformation in a curative vaccine at once totally lost by the action of radium its pathogenic power.

By means of radium we have thus arrived at the basal result of future research, that is to say, to destroy completely the pathogenic power while preserving completely or in a great proportion its vaccinating properties, which in like manner are in evidence to advantage in the preparation of an auto-curative vaccine by which the cancerous emulsion, as in the better viruses, counteracts alike harmful matter and useful matter, distinctly or in reciprocal transformation. We are thus brought back to the ancient touchstone, the spear of Achilles, which had the power of healing the wound which it produced.

Up to now we can say nothing of the properties of this vaccine which we propose to study intensively to know especially its scientific and practical ends; if and how much it maintains its activity; how much in the liquid state and how much in the dry state; whether it be possible or not, its greatest concentration and preservability; if it be possible to succeed in separating it from the inactive and encumbering material; if it acts locally only and in the surrounding zone of the tumour, into which it has been exclusively injected in these tests, or if the same efficacy is verified when the vaccine is introduced into distant parts, because its use should not be limited to tumours which are external or in readily accessible situations.

Equally one cannot speak at this state of the research on the possibility of its application to man, whether, that is to say, one can prepare an auto-vaccine for human use which will have an effect equal to that prepared for mice.

For this purpose there will still be opportunity to determine in priority the question whether every vaccine would possess specificity exclusively for the tumour from which it was derived or whether the vaccine from a tumour would possess the polyvalency necessary to be of service for more varieties of tumour.

In the first sense, we shall speak of the failures in man of the therapy found useful for tumours in animals; in the second, the parimmunity brought to light by the researches of Ehrlich, and, more particularly, by the recent studies of Gye and Barnard, which indicate that the oncogenous virus is constituted by the necessary co-operation of two factors, one specific and one general. In our case the vaccine may be attached either to the general factor, and then its task will be rendered extremely easy, or to the specific factor, and will then encounter in its attenuation the very greatest practical difficulties sometimes insurmountable, and it will be, above all, necessary to establish a careful selection of the radiation useful in the special case, among which the manifold nature that analysis reveals emanates from the radio-active substance.

Hence, without wishing to revive excessive illusions, at present we can only say that our actual experience offers at least a first solid support for the continuance of the research up to the point at which the results obtained authorize us to try the test in man, and in the meantime to furnish once again the demonstration that here is opened one way to arrive with well-founded hope at the solution of a cruel problem which is at once scientific and humanitarian.

A STUDY OF SOME REMOVABLE CAUSES OF UNEMPLOYMENT AND CRIME.

By F. G. Cawston, M.D.Cantab.

(Read at the Congress of the S.A. Association for the Advancement of Science, held at Oudtshoorn, C.P., July, 1925.)

PSYCHO-ANALYSIS is of little practical value, except as it has taught us means of preventing delinquency and mental disease and has revealed causes of unemployment and crime which can be removed.

Unemployment, crime, the native question and the missionary programme may be regarded either as of academic interest only, merely as nuisances to the well-to-do citizen, or as providing a task for those who are prepared to take their share in the solution of these problems, by emphasizing a need which they can in part supply. It is a cause for satisfaction that the Government is tackling the whole subject of unemployment so bravely and is endeavouring to separate the various classes of unemployed, which will ever remain as a problem for the Government, the municipalities, philanthropic bodies and the individual.

Efforts have sometimes been made to find employment for all, without due consideration of the ability of the unemployed workman. In some instances unemployment, like crime, must be regarded as a disease for which there is a sufficient explanation, if this is sought for; and, sometimes, the cause can readily be removed by appropriate treatment.

Among the *physical causes* of unemployment which I have encountered whilst acting as a member of the Juvenile Affairs Board at Durban may be mentioned: squint, nystagmus, osseous growth at the knee (removed by operation), short sight (corrected by spectacles), bilharzia disease in a mentally deficient lad, deafness, advanced dental caries in a lad complaining of the cigarette craving and under a suspended sentence for the theft of bicycles, deflected nasal septum (requiring operation), extensive nasal discharge (cured by nasal douching), flat foot.

Any of these conditions may conceivably lead to either unemployment or crime.

As the liquor craving is commonly associated with crime in the adult, so the cigarette craving is sometimes associated with crime in the juvenile adult. My experience in general practice convinces me that, in many cases, the lure of liquor may partly be explained by indigestion due to dental caries or to a persistent high blood-pressure, and that an incorrect

diet may often lead to a craving either for liquor or for cigarettes.

One gentleman requested me to get his wife of 72 into an inebriates' home; but I found her condition quickly responded to treatment, when three decayed teeth had been extracted and an acid condition of the stomach had been corrected.

It has been suggested that some form of *moral instruction* be given as part of the school curriculum in Natal. The lack of commercial morality, gentlemanly behaviour in public and respect of parents must be regarded as essential causes of delinquency among juveniles in the present day. The rushed meals and lack of real home life tend to lessen a child's respect for its elders.

A mother once complained to me that her boy was repeatedly stealing *her* cigarettes!

Then I do not see how it is possible to deal with the case of the released prisoner or with the juvenile who is placed under a suspended sentence, until some further efforts are made to compel them to pay back what they have stolen or, by other means, to get right with those they have wronged.

Attention has recently been given to the desirability of imparting definite information in regard to the *sexual life* to those boys and girls who attend the Government schools in Natal. The vast majority of young persons derive their first knowledge of sexual relationship from their companions, either at school or at the cadet and scout camps, and many of them are exposed to the conversation of natives about these matters on their way unattended to school or on their way home. The increase of divorce and the large number of children who have been rendered fatherless as a result of the recent war has accentuated the problem; for a growing lad needs a father as much as he needs a mother. Parents tend to forget that, as a rule, children have few of those evil ideas associated with sexual things which are common in later years.

Some teachers hold that conscience is a sufficient guide for the school-child; though most teachers of experience are wide awake to the tendencies towards sexual indiscretion that exist in schools and *do* give occasional words of warning to their scholars. Although it is dangerous to allow a child to leave school without some definite instruction in regard to the sexual life, it is difficult to see how each can be reached individually.

A lad was brought to me who had been up before the Durban magistrate for sexual crime. Up till the age of fifteen, when he left school, he had taken no interest in sexual things; but, being out of work for a few months after leaving school, he had been led to indulge in what he believed to be the practice of married persons. In this case there would appear to be little fear that he would continue as he did, as soon as his ideas of sexual things had been corrected.

There are some strong reasons against sexual instruction in schools being entrusted to the unmarried lady school teacher, and I have great doubts of the value of those portions of botany and natural science which have been chosen to prepare the child's mind for the sex problem as it affects the human race. It would be better to make such instruction more thorough and to confine it to the older children. It is most important that sex instruction in schools should contain nothing that is contrary either to science or to scripture, and that means that those who are to impart it must have a thorough knowledge of both. It is the lack of these two essentials that is responsible for practices which no true scientist or God-fearing person could entertain for a moment. What veterinary surgeon would entertain the possibility of tearing away the "after-birth" before it is properly formed in the womb, or would attribute a strong fertility on the part of the male to lack of control? Yet these are views which are held far too commonly and little is done to counteract them.

Those who advocate the definite education of our rising generation as to the principles of the sexual life must guard against the tendency to overeducate; for an outlet is needed for the sexual instinct of young people which is quite independent of reason. There are some valuable instincts associated with the sexual part of our being, such as modesty, migration and the desire to possess what is pleasing. These may run riot if left to themselves, and every boy and girl needs to be safeguarded against the possibility of these instincts carrying them into wrong channels.

So far, sexual instruction in schools has been rather of a corrective than of a positively instructive nature. It has been general to regard all manifestations of the sexual nature as wrong and requiring restraint. This has caused endless anxiety in many earnest young persons; for, throughout their school years, they have been given to understand that all sexual thoughts are necessarily impure ones.

Unemployment is an important cause of juvenile delinquency, and, although it is difficult to see how best to lessen the obvious results of overcrowding and the undesirable home surroundings in which many juveniles are placed, mention should be made of the large number of families which are drifting into the towns, through lack of employment on the farms, and the tendency of such persons to engage in liquor-selling to natives and Indians with the regrettable influence which such illegal practices must have on their children.

Efforts have been made to get into touch with all juveniles who come before the Durban courts and are known to be living in undesirable surroundings, and, in various parts of the Union, hostels are being formed for young persons who have no homes of their own, whilst looking out for employment or until such time as they may become self-supporting. Particular attention should be paid to juveniles under a suspended sentence, or to those who have associated with criminals in or out of gaol.

Conclusions.

(1) Although unemployment and crime must be recognized as insoluble problems under present conditions, there is often some physical or mental cause for them and this should be investigated and, where possible, removed by appropriate treatment.

(2) It is most desirable that juveniles be urged and assisted in their efforts to get right with those they

have wronged; even, if necessary, by working off their dues under Government supervision.

(3) In view of the sexual cause of much crime, the present methods of preparing young persons for the sexual life require revising, so as to safeguard the juvenile delinquent from those temptations to which he is particularly exposed.

CORRECTION.—In Dr. J. M. Fiallos's paper, published in *Journal of Tropical Medicine and Hygiene*, December 1, 1925, on "Castellani's Fermentation Phenomenon," the paragraph *B. typhosus* + *B. morgani* + *B. proteus* (p. 427) should read as follows: "*B. typhosus* alone produces acidity, never gas; *B. morgani* produces neither acidity nor gas; the mixture of the three germs produces gas."

A Comparison of the Khan with the Wassermann Test (Mildred H. Faupel, *Bulletin of the John Hopkins Hospital*, September, 1925).—The value of the Khan precipitation test for syphilis was studied in specimens of blood from 400 patients in comparison with the Wassermann test. Of these, 90·2 per cent. showed absolute agreement, 3·8 per cent. good relative agreement, 5 per cent. partial agreement, and 1 per cent. absolute disagreement. The co-efficient of correlation for the series was found to be 0·79. The method is comparatively simple and the reaction is completed within five to thirty minutes after mixing serum with antigen. The test is of especial help in cases in which the rapidity of obtaining results is an important factor. The test has not been found applicable to spinal fluids.

Lichenoid Sarcoid. An Unusual Case (Carroll S. Wright, M.D., *Archives of Dermatology and Syphilology*, September, 1925).—The case described in this paper presented a most unusual form of sarcoid; it appeared at first as areas of loss of pigment in which lichenoid plaques develop. The condition was associated with a pulmonary tuberculosis, which apparently developed four years after the appearance of the cutaneous manifestations. There still seems to be doubt as to the tuberculous nature of sarcoid. Until recently no one had reported the finding of the tubercle bacillus in sections of tissue from the nodules. In 1921 Kyrle was able to demonstrate the organism by staining in sections made from patches examined within ten days of their appearance. After this time they disappeared. Kyrle was unable to demonstrate the bacillus by animal inoculation. It was his opinion that the lesions were caused by foci of bacilli in the skin producing a focal reaction, the bacilli disappearing soon after the onset of the reaction. This work requires confirmation.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

Tropical Medicine and Hygiene

DECEMBER 15, 1925.

MALTA FEVER AND INFECTIVE ABORTION.

AT a recent joint discussion of the Sections of Comparative Medicine, Obstetrics and Gynæcology and Tropical Diseases and Parasitology, at the Royal Society of Medicine, the subject dealt with was

Infective Abortion in Cattle and its Relation to Malta Fever.

In opening the discussion, Professor John Eyre pointed out that during the past decade a number of observations and experiments relating to *Bacillus abortus* on the one hand, and the organism which is regarded as the causative factor in the production of undulant or Mediterranean fever on the other, appear to indicate that the relationship existing between these bacteria is extremely close and suggest a new interpretation of results obtained by earlier workers. The trend of present-day opinion is to regard these two organisms as identical or so closely allied as to be included into one group or genus to which the name *Brucella* has been given.

Culturally, morphologically, and in their biochemical reactions the two organisms are indistinguishable, and attempts have been made to differentiate them by serological means, such as agglutination, complement-fixation and absorption tests. Eyre, however, while drawing attention to the tendency there was to make a diagnosis of identity upon serological grounds alone, contends that serological groupings are not all-important.

It was long considered that undulant fever was restricted to Malta and the Mediterranean littoral, so that Malta fever and Mediterranean fever were employed as synonyms for the disease. Further experience showed the malady to prevail far inland in Italy, France and Spain. It has also been recognized in India, Asia, Africa and America, and sporadic cases are also now being occasionally met with in England, so that the disease may now be considered world-wide in its distribution.

An ætiological study of the relationship between Malta fever and infective abortion produces somewhat conflicting results.

As long ago as 1911 it was shown that the *B. abortus* was present in a large percentage of samples of cow's milk submitted to guinea-pig inoculation and that the organism was excreted by the animal even when there was no obvious lesion of the udder. Soon afterwards the sera of some children were found to react positively with the *B. abortus*, and this may be correlated with the fact that children constitute the great proportion of the milk-drinking individuals in a community. It was then found that the milk of some London cows possessed the power of agglutinating laboratory cultures of *Micrococcus melitensis* and it is now believed that the agglutination is probably dependent upon the amount of infection of *B. abortus* present in the cows, and it seemed difficult to imagine that the English strain of this organism could be virulent for man.

The knowledge of these facts led to inquiries being made into the possibility of the infection of man by *B. abortus*, and it was shown that the serum of some individuals would agglutinate this organism in fairly high dilutions. Negative results, however, were obtained on injecting both men and monkeys intravenously with large doses of living *B. abortus* cultures. An investigation also into the complement-fixation reactions towards this organism in cases of abortion in women yielded completely negative results.

In some parts of Austria the contagious abortion of cattle is stated to be rife in districts in which undulant fever has not yet been observed in man. Further, pregnancy and Malta fever frequently coincide without abortion supervening, though lactation may be somewhat curtailed.

Careful recent work in Rhodesia, on the other hand, shows that in that country, and particularly in Southern Rhodesia, cases of undulant fever occur in men, women and children who cannot have become infected from goats, but who reside, or have resided, on farms or areas where cattle are, or have been, infected with the organisms causing infectious abortion. If this association can be verified in one country, it will undoubtedly be found to exist wherever these diseases are encountered. If, then, this insidious disease of cattle which is now known to be world-wide in its prevalence can, in any circumstances whatever, become infective to man, it is a matter of the greatest importance, and demands the most careful consideration. There are, however, still too many inconsistencies and discrepancies urgently calling for investigation, and many links must be added to the chain of evidence before we can give whole-hearted support to the view that *B. abortus* and *Micrococcus melitensis* are identical organisms, with all that the view connotes.

F. E. T.

Annotations.

Biological Investigation of California Rice Fields and Attendant Waters with Reference to Mosquito Breeding (W. C. Purdy, *Public Health Bulletin*, December, 1924).—Aside from the several findings which are stated, the two years' biological investigation in California presents one or two outstanding items of more interest than is usually accorded to routine results. The interest in the matter attaches partly because the information referred to is unexpected and out of the ordinary, and partly because of the human interest involved, the possible public health effects. The first item is the practical absence of mosquito breeding on the Nelson rice field. This fact was established by persistent and continuous collections during the entire rice-growing seasons of 1919 and 1920. Meantime, nearby puddles and ditches showed breeding, and, during the second season, when three additional rice and four additional ditches were included, all these showed breeding. The Nelson rice field alone stands out from all the other fields and related waters by reason of the radical difference it exhibits in that it practically fails to breed mosquitoes. This failure suggests the presence of some natural agency which operates to inhibit breeding. Such a natural agency would, it is needless to say, be a thing greatly to be desired. The second item is the apparent results of the search, during the second season, for the probable reason for lack of breeding in the Nelson field, an inquiry as to just what this natural inhibitive

agency might be. To this end a careful comparison of the Nelson field with all the other fields and puddles seems to indicate no considerable or essential difference in:

(1) Number of larval enemies.
(2) Relative amount of food supply.
(3) Temperature.
(4) Alkalinity of water.
(5) Free CO_2.
(6) Dissolved oxygen; or
(7) Relative stability.

The study of the alga growths, however, does reveal a difference which appears to be as fundamental and as well marked as is the contrast in breeding. The Nelson field contains a very heavy growth of a blue-green alga which is not found, except in rare instances and in very minute quantities, in any of the other fields or waters examined. Other algæ appear on the Nelson field in very small amount only. Moreover, this same blue-green (*Tolypothrix*) was similarly prevalent on the Nelson field in 1919. Further testimony concerning the apparently larvicidal effects in water containing this alga is furnished by the field tests and these effects seem potent not only for very young larvæ, but also for vigorous, half-grown ones; and, finally, the water in the feed canal (before coming in contact with this alga) is found to be favourable for larval development. Meantime, no explanation is yet available as to the manner in which the larvicidal agency acts. While definite conclusions may not safely be drawn from the field tests, which were carried out during one season only, yet it is permissible to say, pending further research, that there exists a possibility and even a probability that the lack of mosquito breeding on the Nelson rice field—in which matter it differs fundamentally from all the other waters examined—may be related in no small degree to the other outstanding difference which this same field exhibits, in that it contains a heavy growth of the blue-green alga *Tolypothrix*.

Radium Therapy in Dermatology (G. Allen Robinson, M.D., *American Journal of Roentgenology and Radium Therapy*, August, 1925).—In this paper the author gives his experiences with radium in the treatment of keloids, birthmarks, lupus erythematosus, verruca and epidermoid carcinoma of the skin. Keloids can be successfully treated by this method, but response to treatment varies with the size, thickness, consistency, rate of growth and duration. Recent, small, soft, rapidly-growing keloids in young subjects respond most quickly and with the best end-results. Surgical removal of large keloids, with post-operative irradiation to prevent recurrence, is suggested. Splendid results are obtained in the treatment of cavernous angioma and port wine marks, provided careful methods of radium application are used. The results of treatment of pigmented moles have not been satisfactory; cases of melanomata have responded well. Verrucæ are radio-sensitive and one treatment is generally sufficient to remove the lesions. Epidermoid carcinoma of the skin and lupus erythematosus are greatly benefited by radium treatment.

Leukoderma following Dermatitis Venenata (*Rhus toxicodendron*) (Lee McCarthy, M.D., and Lawrence K. McCafferty, M.D., *Archives of Dermatology and Syphilology*, September, 1925).—Kaposi first pointed out that leukoderma may follow various cutaneous eruptions. For many years syphilis has been accused of being the sole cause of this form of leukoderma, but a sufficient number of cases have been reported subsequent to psoriasis, parapsoriasis, pityriasis rosea, lichen planus, seborrhœic eczema, lichen simplex chronicus, &c., in order to dispel all doubt as to the non-specificity of leukoderma. The explanation of the production of this depigmentation is not clear in the case described in this paper as in those following the various diseases mentioned above. It is known, however, that leukoderma following syphilis, psoriasis, &c., originates on those lesions which have been but slightly infiltrated; such is the case in the lesions of dermatitis venenata. The question naturally arises whether one is dealing here with a true primary leukoderma due to a derangement of the pigment function of the skin areas invaded by the toxins of *Rhus toxicodendron*, or a pseudo-leukoderma resulting from exposure to the affected parts of the rays of the sun. Brandweiner believes that leukoderma following syphilis is due to a temporary derangement in function of the pigment-forming cells resulting from the action of the syphilitic virus. It seems plausible to believe that the toxins of *Rhus toxicodendron* could produce a similar disturbance in the function of the pigment-producing cells of the involved areas. The authors' belief is further strengthened when it is recalled that in their case the lesions of dermatitis venenata had completely healed ten days before exposure to the sun. Accordingly, it may be concluded that in the case described in this paper a true or primary leukoderma is being dealt with. Leukoderma has been repeatedly treated with Alpine light. In general the result has been disappointing. This form of treatment was resorted to in the case described. Five treatments were given at intervals of three weeks. A mild erythema over the involved area was produced at each visit. Judging from the amount of improvement which took place during a month it is believed that the achromia will be completely cured within a short time.

Observations on the Sigma Reaction for Syphilis (H. Everett Smiley, M.D., *Archives of Dermatology and Syphilology*, September, 1925).—From the results of the experiments described in this paper the

following conclusions may be drawn: The Sigma reaction offers a reliable index in following the effect of a course of treatment for syphilis. The validity of the Sigma reaction is apparently not affected by treatment. Much more information can be gained from a course of Sigma readings than from a similar course of Wassermann readings.

Immunological Reactions of the Isolated Carbohydrate and Protein of Pneumococcus (Oswald T. Avery, M.D., and Hugh J. Morgan, M.D., *The Journal of Experimental Medicine*, September 1, 1925).—Investigations have proved that the isolated carbohydrate of pneumococcus is non-antigenic in the sense of stimulating antibody formation. The isolated protein of pneumococcus is antigenic; it induces the formation of antibodies which react with nucleoprotein fractions of organisms of homologous and heterologous types. The antiprotein sera do not agglutinate type-specific strains of pneumococcus, or react with the carbohydrate derived from them.

The Antigenic Properties of Solutions of Pneumococcus (Oswald T. Avery, M.D., and James M. Neill, Ph.D., *Journal of Experimental Medicine*, September 1, 1925).—It is found that intact pneumococci, possessing specific antigenic powers unimpaired by cultural or other procedures, give rise to agglutinins for organisms of the homologous type and to precipitins for the type-specific carbohydrate derived from them. Solutions of pneumococci free of all formed elements, but containing the carbohydrate and protein of the original cell, fail to stimulate the formation of type specific antibodies. Sera prepared in this manner do not react with the carbohydrate constituent of the cell and do not agglutinate organisms of the homologous type. The loss of this antigenic function is related to changes incurred during dissolution of the bacterial cell. Solutions of the cellular substances of pneumococcus, although lacking the specific antigen of the whole cell, induce the formation of antibodies reactive with pneumococcus protein regardless of the type from which the latter is derived.

Cause of Nitritoid Crisis following Intravenous Injection of Arsenicals (Ernest Friedrich Müller, M.D., *Archives of Dermatology and Syphilology*, September, 1925).—It was observed that the patients who reacted to arsphenamin with unusual symptoms of a nitritoid crisis and those who showed equally unusual symptoms after injections of silver arsphenamin, i.e., a decrease in the number of leukocytes in the blood with or without visible manifestation, will also react positively to the Widal test without showing any apparent sign of hepatic involvement. Following the studies described in this paper on the causes of Widal's hæmoclastic crisis and entirely independent of any possible hepatic involvement which would entail an abnormal condition of the involuntary nervous system, it must be assumed that in the seven patients with a positive reaction, even the simple act of taking nourishment leads to an abnormal reaction of the leukocytes and of the involuntary nervous system. The fact of the presence of the Widal hæmoclastic crisis is proof that abnormal conditions exist in these patients. This confirms former conclusions that the unusual reaction in the blood following injections of silver arsphenamin into patients who also show symptoms of a nitritoid crisis after administration of arsphenamin is not due to the drug, but rather to a pathological reactivity of the involuntary nervous system. This abnormal reactivity, latent in the body before injection and manifested by an unusual reaction of the body itself, is due to a disturbance of the involuntary nervous system.

The Wassermann Test. XV.—The Effect of Bismuth on the Wassermann Reaction in Patients Unresponsive to Arsphenamin (Archives of Dermatology and Syphilology, September, 1925).—It is found that bismuth lowers the strength of the Wassermann antibody not only in patients who are responsive to arsphenamin, but also in those who are unresponsive. The average reduction in this series, composed largely of arsphenamin-resistant patients, was 39 per cent., which probably represents the minimum effect of bismuth. Nine-tenths of the reduction was obtained four weeks after the end of treatment, and the remaining one-tenth by the sixteenth week. In patients with old syphilis bismuth does not give any slower serologic action than the arsphenamins. The reduction would appear to be permanent, at least it was found to be permanent for the six months the patients were under observation. The few patients who showed a relapse received less than the standard dosage.

Variable factors, such as the strength of the reaction, the clinical stage and duration of the disease and the total dosage, which usually render serologic interpretations of doubtful value, exerted a negligible influence in this particular series and permitted direct comparison between patients responsive and unresponsive to arsphenamin. However, the extent of the reduction of the Wassermann antibody corresponded to the intensity of treatment. All the Wassermann-fast patients in this series had shown no change in the strength of the Wassermann antibody under treatment with arsphenamin. One-half of these patients reacted to bismuth as compared with five-sixths of the patients who were responsive to arsphenamin. Also the quantitative reduction of the Wassermann antibody in these patients was one-half of that of the arsphenamin responsive patients. After the first course of treatment the total amount of arsphenamin and mercury administered had no apparent influence on the action of bismuth.

Chemotherapeutic Experiments with Chaulmoogra and Allied Preparations (Otto Schobl, *Philippine Journal of Science*, April, 1924).—No disinfecting effect was shown upon acid-fast bacteria by the vapours of chaulmoogra and *Hydnocarpus* oils, but the volatile constituents of certain essential oils show high disinfecting activity with a strong indication of selectivity toward acid-fast bacteria.

The Preparation of Endo's Medium (Norman MacL. Harris, *Military Surgeon*, September, 1925).—The author is of the opinion that the following factors produce a satisfactory Endo medium. As a basis, Levine's formula, which does away with one of the root troubles, namely, meat extract. A basic fuchsin containing both rosaniline and pararosaniline; other fuchsins are productive of irregular results. A hydrogen-ion concentration within the limits of pH 7·4 to 7·6. Any peptone that will give with Levine's formula a vigorous growth; "Difco" is highly recommended.

Diabetic Retinitis (Harry Friedenwald, M.D., *Journal of the American Medical Association*, August 8, 1925).—Diabetic patients developing retinitis generally present the punctate form which is most marked in the region between the superior and inferior temporal vessels, but may extend to other parts of the retina. The spots are usually small, but may coalesce into lines or even large masses. They are usually accompanied by fine hæmorrhages. The optic discs are of clear outline; there are no signs of retinal œdema, and ill-defined "cotton-wool" spots are rarely found. Other conditions—thrombosis of the retinal vein, retinitis proliferans and profuse hæmorrhages — are of rare occurrence. Retinitis punctata centralis was found in thirty-three cases with diabetes, and in eighteen without diabetes, of which latter nine showed evidences of nephritis. At most only nine cases could therefore be certainly classified as arterio-sclerotic retinitis. The view of Foster Moore, that this form of retinitis is primarily due to arterio-sclerosis, would lead us to expect to find it frequently, much more frequently without diabetes than with it, because of the vastly greater number of arterio-sclerotic patients who are free from diabetes than those who suffer from it. But as seen in the series described in this paper, quite the opposite is the case, diabetes being found almost twice as often as absent. Nor does this take account of the fact that the cases classed as "non-diabetic" were not examined as to blood-sugar, and in many of the cases a single examination had to suffice. Hirschberg and others have found retinitis punctata centralis in cases in which no sugar was found at the first examination, and it required repeated examinations to discover it. Again, this does not take into account the well-known fact that in old cases of diabetes traces of sugar may be lost after nephritis has become established. The view is justified, therefore, that retinitis punctata centralis, whilst not pathognomonic of diabetes, is indicative of this ætiologic basis. When found in the presence of diabetes, or even of diabetes with nephritis, it may with propriety be designated as diabetic retinitis. Others have stressed the appearance of profuse retinal hæmorrhages in diabetes. The foregoing cases do not bear this out. The retinal hæmorrhages found are generally punctate. Abundant hæmorrhages are rare.

Parenchymal Râles in Pulmonary Tuberculosis (E. H. Bruns, M.D., *Journal of the American Medical Association*, September 5, 1925).—Showers of fine and medium râles of equal size, occurring at the end of a full inspiration, or the so-called coughing râles which occur when the patient forcibly breathes out, gives an expiratory cough and immediately breathes in, are not due to the bubbling of secretions in the alveoli or bronchial tubes, nor are they necessarily associated with abnormal secretions in these structures. Such râles are not always associated with active inflammatory processes in the pulmonary parenchyma or bronchi, and must be distinguished from tracheal, bronchial, cavity and pleural râles. Parenchymal râles cause the most confusion. They may be due to pneumonia, fibrosis, atelectasis, pleurisy, &c., and cannot be said to be associated with any particular disease or pathologic condition. Showers of râles usually elicited only by cough and heard over the upper parts of the lungs are unquestionably the most reliable physical sign for the detection of tuberculous lesions. The significance of these râles as a criterion of manifest tuberculosis and the character of the lesions will depend on other clinical findings —history, symptoms, sputum, roentgen-ray examination. A period of observation may be necessary in order to arrive at a definite diagnosis. In studying the progress of a case and in deciding whether a tuberculous process is progressing or undergoing retrograde changes, the persistent occurrence of this type of râle is not a conclusive sign unless correlated with other physical signs and clinical findings.

Argentine Tumours of the Appendix and Small Intestine (Wiley D. Forbus, M.D., *Bulletin of the Johns Hopkins Hospital*, August, 1925).—Attention is called to the fact that the term "carcinoma" has been erroneously applied to a group of small tumours occurring either singly or in numbers in the appendix and small intestine, and which bear a morphological similarity to true carcinoma of these organs. In six cases of so-called "carcinoma" of the appendix and small intestine, the argentaffine or chromaffine character of the cells of these tumours, originally described by Gosset and Masson, have been confirmed. The "car-

cinomas " or " carcinoids " of the appendix and small intestine have their origin in the cells of Kultschitzky and Schmidt of the crypts of Lieberkuhn and, therefore, are tumours of the chromaffine system. They may be spoken of as argentaffine tumours, in view of the peculiar ability of the granules of the tumour cells to reduce an ammoniacal solution of silver. The importance of differentiation between the argentaffine tumours and a peculiar form of adenocarcinoma of the appendix and small intestine, which is superficially similar to the argentaffine tumours, is emphasized. Attention is called to the general harmless character of the argentaffine tumours.

Studies on the Relation of Insect Herpetomonad and Crithidial Flagellates to Leishmaniasis. 1.—*Inoculation of Mammals with Insect Flagellates* (Jaroslav J. Drbohlav, M.D., *American Journal of Hygiene*, September, 1925).—The inoculation of *Herpetomonas ctenocephali* of the dog-flea, from both old and freshly isolated cultures, into warm- and cold-blooded animals, i.e., mouse, rat, rabbit, dog, monkey and frog, has invariably proved unsuccessful. The flagellates inoculated became rounded in about one hour and then degenerated and diminished in number, so that after six hours very few were present. No forms were found after twenty-four hours. Up to three hours after inoculation the flagellates could usually be recovered in culture. Material from the water strider, *Gerris remigis*, infected with *Crithidia gerridis*, was inoculated into mice, rats and frogs without success. No forms were found in preparations or recovered in cultures from animals examined at intervals of from 1 to 150 days. The inoculated flagellates disappeared after six hours. *Herpetomonas muscarum*, from the gut of flies of the genus *Lucilia* and from freshly isolated cultures, was inoculated into mice, rats and frogs without producing infection. The same monkey used for the inoculation of flea flagellates was inoculated subcutaneously, with negative results. Several species of plants of the genus *Euphorbia*, found in the Botanical Gardens in Cambridge, Mass., and one species of *Asclepias* growing abundantly in the vicinity of Boston, were all found free from flagellates. In hanging-drop preparations of latex from these Euphorbiaceæ inoculated with *Herpetomonas ctenocephali*, *H. muscarum*, *Leishmania infantum*, and *Trypanosoma rotatorium*, motile forms were present after a period of five days, but no multiplication took place. All the forms degenerated and were dead after six days. The Euphorbiæ were inoculated with different cultures of herpetomonad flagellates, but no forms were found in the latex, although examined daily for a period of thirty-five days. In none of the animals and plants inoculated was there any indication of multiplication of the flagellates within the body, but on the contrary these diminished in number and disappeared after a few hours. The positive results reported by others may be explained by a confusion of natural infections for the inoculated, especially since proof, such as might be obtained by isolation in culture of the flagellate inoculated is lacking. The author's experiments would indicate no ætiological relationship existing between the insect herpetomonads, *H. ctenocephali*, *H. muscarum*, and *C. gerridis*, and Leishmaniasis, and the author's results confirm those obtained by American and the majority of European investigators.

Studies on the Relation of Insect Herpetomonad Flagellates to Leishmaniasis. II. *The Specificity of the Various Insect Flagellates for Certain Hosts, as indicated by Cross-Infection Experiments* (Jaroslav J. Drbohlav, M.D., *American Journal of Hygiene*, September, 1925).—Cross-infection experiments show that fleas may be artificially infected with their natural parasite, *Herpetomonas ctenocephali*, but not with *Leishmania infantum*, *Herpetomonas muscarum* or *Crithidia gerridis*. Larvæ of the dog-flea, *Ctenocephalus canis*, were artificially infected by feeding them with fæces of infected fleas and with cultures of *H. ctenocephali*. Since such infected larvæ remained infected throughout the entire larval, pupal and adult stages of development, it appears probable that the natural infection of fleas is acquired in the larval stage by feeding on infected fæces of adult fleas, and not in the adult stage when only animal blood is taken as food. Attempts to infect flagellate-free *Gerris remigis* with *H. ctenocephali*, *H. muscarum* or *L. infantum* proved unsuccessful. Attempts to infect clean flies by feeding them the *H. ctenocephali*, *L. infantum* and *C. gerridis* failed. Cross-infection experiments carried out with cultures of *H. muscarum* on certain species of flies of the genera *Musca*, *Fannia* and *Lucilia* have furnished positive results, all of these species serving as suitable hosts. This, in the absence of any other differential character, indicates that the flagellates described as different species from these various flies represent one and the same organism. Therefore the name *Herpetomonas muscarum* applies to herpetomonads found in different species of flies.

Studies on the Relation of Insect Flagellates to Leishmaniasis. III.—*Cultivation Requirements* (Jaroslav J. Drbohlav, M.D., *American Journal of Hygiene*, September, 1925).—Experiments to determine the growth requirements of different flagellates have shown that the pH concentration of medium is a very important factor in the cultivation. The flea flagellate gave the maximum growth at a pH of 6·8, whereas the fly flagellate grew best at pH 5·4 to 5·6. The best culture of *Leishmania* was obtained at 7·0. The parasites showed also some variations in form upon media with different reaction. In the case of *Herpetomonas ctenocephali*, characteristic twisted forms were abundant at pH 5·6 to 6·2, whereas in higher concentra-

tions shorter forms, with few or no twists, were present.

From the experiences of the present study of different constituents of media used for cultivation of herpetomonad flagellates, a slight modification in preparing media and handling cultures is given. On such media all strains of herpetomonad flagellates used in the present investigations were readily kept for the period of one year without transfer; successful subcultures were obtained.

The Penetration of Fruits and Vegetables by Bacteria and Other Particulate Matter and the Resistance of Bacteria, Protozoan Cysts and Helminth Ova to Common Disinfection Methods (Ralph G. Mills, M.D.; Clifford L. Bartlett, M.D., and John F. Kessel, Ph.D., *American Journal of Hygiene*, September, 1925).—It is found that normal uninjured fruits and vegetables do not contain living bacteria within their tissues. Finely divided particulate matter, such as carbon, corresponding in size to bacteria, protozoan cysts and helminth ova, does not penetrate the stem-end of fresh vegetables to any appreciable extent. Bacteria do not penetrate the unbroken skins of fruits and vegetables, kept under market conditions. Bacteria pathogenic to man may gain entrance to fruits and vegetables through injured and decayed portions, where they may spread to a very limited extent, and may remain alive for seven to forty-two days. They may also contaminate the cut-end of vegetables and remain viable for a similar length of time. It is, therefore, advisable to remove such portions before attempting sterilization. Pathogenic bacteria may persist on the surface of fruits and vegetables kept under moist conditions, for fifteen days or more. The gradual loss of moisture through the covering of fruits and vegetables would tend to keep them viable longer than would be possible on perfectly dry surfaces. When such food-stuffs are freshened with water, the viability would be influenced by the saprophytic flora normal to such an environment. Chlorination freed the surface of vegetable matter from pathogenic bacteria in every instance, but was not effective against cysts or ova. Alcohol is ineffective in killing all protozoan cysts and helminth ova in sufficiently short periods of time to make it valuable as a disinfecting agent. Potassium permanganate in the concentrations ordinarily used is not an effective disinfectant against helminth ova and protozoan cysts.

Burning alcohol on the surface of fruits and vegetables, or pouring boiling water over them does not destroy all pathogenic organisms, either bacteria, cysts or ova. The heat does not sufficiently penetrate the crevices. Dipping fruits and vegetables for ten seconds into boiling water or water which remains above 80° C. during the immersion, is the only method thus far discovered which will uniformly kill all pathogenic bacteria, protozoan cysts, and helminth eggs which might be found contaminating such food-products, and render them safe for human consumption in an uncooked condition.

Roentgen-Ray Treatment in Bronchial Asthma and Chronic Bronchitis (Issac Gerber, M.D., *Journal of the American Medical Association*, October 3, 1925).—It is found that many cases of true bronchial asthma do not respond to the removal of supposed extrinsic causes or to specific therapy, even though careful sensitization tests have been made. A large proportion of these patients may be markedly benefited by careful Roentgen-ray treatment. In favourable cases there is a lessening, and even disappearance, of the paroxysms and cough, a change in the amount and character of the sputum and a diminution of the abnormal microscopical elements in the sputum. Two types of Roentgen-ray applications are used, one directed to the mediastinum and chest, and the other to the spleen. The mediastinal treatment probably has its effect, though a shrinking action on the rays on the enlarged tracheo-bronchial and mediastinal lymph nodes, with subsequent diminution in the irritability of the local fibres of the vagus nerve. The mechanism of the effect through splenic exposure is not so clear, but may possibly be concerned with the release of antibodies which modify the anaphylactic seizure. Chronic bronchitis without asthmatic attacks can also frequently be helped by application of Roentgen rays to the mediastinum. The most favourable results are obtained in younger people, particularly in children who have persistent coughs after attacks of grip or pertussis. Cases of secondary bronchiectasis that are not of surgical extent may be improved when other treatment is ineffective.

Study of a Hemolytic Proteus Bacillus (B. S. Kline, *American Journal of Hygiene*, September, 1925).—A proteus bacillus, highly pathogenic for rabbits, was isolated forty-eight hours post mortem from human bone-marrow. The organism grows well on ordinary media, has a fairly characteristic sugar reaction and unusually great hæmolytic power. The blood-picture was followed in eighteen inoculated animals, smears showing the appearance in the circulation of a moderate number of nucleated red blood-cells, usually within forty-eight hours. Megaloblasts, also in moderate numbers, were occasionally observed. Animals inoculated with repeated, increasing doses of the organism, over a period of a few weeks, developed a siderosis, more marked in the spleen and bone-marrow, moderate in the liver. A hyperplastic bone-marrow was found in the majority of the inoculated animals.

Proteus Hæmotoxin (E. E. Cker and H. H. Brittingham, *American Journal of Hygiene*, September, 1925).—The hæmotoxin of a culture of *Proteus* isolated from human bone-marrow was studied. The hæmotoxin was produced in broth

and synthetic medium cultures. The toxin rapidly hæmolysed human, sheep, dog; cat, guinea-pig and rat erythrocytes. Chicken erythrocytes were less rapidly attacked. The production of *Proteus* hæmotoxin varied greatly with the strain employed. The lytic principle was independent of the life of the organism. The organisms were killed by etherization. The cultures remained toxic after cell death. The lytic principle was retained in the filtrate of cultures passed through a Berkefeld candle. This observation is not in agreement with the finding of Braun and Chao Shi-Tsing, who found no hæmotoxic effect following Berkefeld filtration or destruction of the cultures. These authors believe that the hæmotoxin is a constituent of the ectoplasm of the organism and firmly bound to the organism. They claim that non-ciliated *Proteus* bacilli have no hæmolytic capacity. We found the hæmotoxin to be thermolabile. Even as low a temperature as 37° C. weakened it. At 45° C. its power was greatly reduced, and at 55° C. it was completely destroyed. We failed to obtain a "Koch-gift," as demonstrated by Bach, although the author himself claimed the phenomenon to be variable. Witte peptone in certain concentrations inhibited the reaction, a fact also recently demonstrated by Bach. Ultra-violet light greatly retarded its power, depending on distance and length of exposure. Anti-hæmotoxic (rabbit) serums demonstrated a definite neutralizing power if the serum and toxin were first mixed and the cells then added to them. Under similar conditions normal rabbit-serums failed to protect. These anti-hæmotoxic serums did not protect against the action of tetanolysin. During the course of the experiments it was found that an optimum concentration of the serum was necessary, a fact also demonstrated by Braun and Chao Shi-Tsing.

Pyrubrin, a Red Water-Soluble Pigment characteristic of Bacillus pyocyaneus (Percy Davol Meader, Ph.D.; George H. Robinson, Ph.D., and Veader Leonard, M.D., *American Journal of Hygiene*, September, 1925).—All typical strains of *B. pyocyaneus* produce three water-soluble pigments: (*a*) the *fluorescent pigment*, which is yellow by transmitted light and green by reflected light; (*b*) *Pyocyanin*, which is bright blue; (*c*) *Pyorubrin*, which is bright red. The fluorescent pigment is non-specific. Pyocyanin is specific of *B. pyocyaneus*. Pyorubrin is characteristic of *B. pyocyaneus*. Each of these three pigments is derived by oxidation of a specific leuco-base which is formed anaerobically. Each of these three pigments will yield its specific leuco-base on reduction with zinc and hydrochloric acid, while oxidation of the colourless compound thus obtained invariably yields the pigment from which it was derived. Pyocyanin and the fluorescent pigment are indicators. Pyorubrin remains unaffected in colour when treated with acid or alkali. The majority of strains of fluorescent organisms derived from Nature, and which are culturally identical with *B. pyocyaneus*, will produce both pyocyanin and pyorubrin on appropriate media and should therefore be classified as *B. pyocyaneus*. Typical strains of *B. pyocyaneus freshly* isolated from human lesions invariably produce both pyocyanin and pyorubrin in abundance and may be highly virulent, while strains isolated from the environment and old laboratory strains may lose temporarily their power to produce any but the fluorescent pigment, and at the same time become avirulent. Agglutination and absorption tests have failed to reveal any difference among the various strains examined. Virulent strains of *B. pyocyaneus* exhibit a pronounced selective affinity for the genito-urinary organs of laboratory animals.

Comparative Studies of the Action on the Pneumococcus of Bile-Acids and Unsaturated Fatty Acids, found in Bile in the Form of Soaps (Anthony Kozlowski, Ph.D., *Journal of Experimental Medicine*, October, 1925).—Ox-bile contains the soaps of unsaturated fatty acids not only with one, but also with two and more than two double bonds, in a dilution of about 1:600. These substances, when isolated from bile, exert an antiseptic action on the pneumococcus in a dilution of approximately 1:50000, and kill the organism in a dilution of 1:5000 in approximately one hour. As their action is, then, about one hundred times stronger than that of the conjugated bile-acids, their presence in bile should be considered, whereas hitherto it has been entirely overlooked not only by bacteriologists, but by physiologists as well. Since the soaps of unsaturated fatty acids do dissolve the pneumococcus cell in broth culture, Neufeld's conclusion is no longer valid.

The Production of Persistent Alopecia in Rabbits by X-rays of Various Degrees of Hardness (Harry Clarke, Ph.D., and Ernest Sturm, *Journal of Experimental Medicine*, October 1, 1925).—The minimum dose of X-ray, of each of three degrees of hardness, required to produce persistent alopecia of the abdominal skin of normal white rabbits has been studied. 40-kilowat rays filtered by 0·5 mm., 50-kilowat rays filtered by 1 mm., and 70-kilowat rays filtered by 1·5 mm. of aluminium were employed. The 70-kilowat work is unfinished.

Local Immunization of Rabbits to Cutaneous Infection with Staphylococcus Infection (Tracy B. Mallory, M.D., and Alexander Marble, *Journal of Experimental Medicine*, October, 1925).—Bacterial filtrates prepared by the methods described by Besredka did not develop any specific growth-inhibiting factors. Such filtrates produced strictly local immunity of the areas of the skin infiltrated, but such protection was never greater than that produced with the broth from which they were prepared. This immunity was manifest in eight hours and persisted at fifteen days. Transcutaneous treatment by moist dressings soaked in either filtrate or broth were entirely ineffective. Sites of healed

cutaneous lesions show a strictly local and non-specific immunity for a period of five to six weeks. Repeated intracutaneous infection with virulent staphylococci failed to produce a general cutaneous immunity.

Inguinale Hernia: Report of 100 Operations on Korean Patients (A. I. Ludlow, *China Medical Journal*, March, 1925).—This is apparently the first report of hernia in Koreans, but the disease has existed in the country for centuries, according to the Chinese medical books. As yet, no accurate statements can be made with regard to the frequency of hernia in Korea, but it is probably of frequent occurrence. All the patients were Korean males, the youngest at time of operation being two years of age and the oldest 84 years. The acquired hernias varied in their duration from four days to forty-five years, with an average of ten years. There were twelve congenital hernias (found at birth) and eighty-eight acquired hernias (developed after birth). Right hernia was more frequent than left. Strangulation was present in twelve cases. With regard to intestinal parasites in these hernia cases, *Trichuris* was found sixty-five times; *Ascaris* fifty-three; *Ankylostoma* ten times, and *Tænia* in one case. Examination of the sputum showed ova of *Paragonimus westermanii* in twenty cases; *B. tuberculosis* in one case.

A Survey of Human Intestinal Protozoa in Peking, China (J. F. Kessel and R. Svensson, *China Medical Journal*, December, 1924).—During six months fæces-smears from 1,037 individuals were examined; of these 816 were Chinese and the rest were resident foreigners. Among the Chinese, infestations with intestinal protozoa showed the following percentages: *Entamœba nana*, 40·1; *E. dysenteriæ* (=*histolytica*), 29·5; "*Councilmania lafleuri*" 19·2; *E. coli*, 11·7; *Iodamœba bütschlii*, 13·0; *Giardia intestinalis*, 10·0; *Chilomastix mesnili*, 6·0; *Trichomonas hominis*, 4·5. Among the foreigners in Peking the percentages were as follows: *E. nana*, 26·5; *E. dysenteriæ*, 16·5; "*Councilmania*," 14·5; *E. coli*, 11·6; *Iodamœba*, 3·2; *Giardia*, 3·0; *Chilomastix*, 10·0; *Trichomonas*, 2·8. The percentage of infestations with *E. dysenteriæ* amongst Chinese adults was 32·5, and among Chinese children 25·3; and the infestations among foreigners were 25·0 and 1·7 respectively.

Contribution to the Study of the Biology of Anopheles superpictus (B. Grassi, *Rendiconti della R. Accademia Nazionale dei Lincei*, Rome, June, 1925).—*Anopheles superpictus* is present in nearly every part of Italy, but is most frequently found in the south. It is most numerous during the months of July and August, while *A. claviger* is most numerous during May and June. *A. superpictus* was first found in October, 1922, at Sangiovanni Incarico, near Ceprano, where it exists in large numbers. Its chief locality is Saluzzo, chiefly in stables. Like *A. claviger*, these parasites are to be found on walls, ceilings and almost anywhere. The eggs are deposited in lines and are thus easy to count; they are smaller than those of *A. claviger* and *do not present the air spaces which are the general characteristic of anopheles*. The larvæ of *A. superpictus* greatly resemble the description of Edwards with the exception of a few minor details.

Current Literature.

THE AMERICAN JOURNAL OF TROPICAL MEDICINE. July, 1925, and September, 1925. Vol. V.

The Basal Metabolism of a Normal Young Man as affected by a Tropical Residence of One Year (W. D. Fleming).—In this paper the author presents data on the metabolism of a normal white man, 22 years old, seven months after his arrival in Manila and, again, after an interval of thirteen months. The man underwent numerous laboratory tests and physical examinations, and the only abnormality found at any time was a marked degree of astigmatism in one eye. His habits and mode of life were normal and regular both in the States and in the Tropics. For the first series the basal metabolic rate averaged 3 per cent. minus, for the second series 7 per cent. minus.

Hookworm in Palestine (A. Felix).—These investigations were carried out early in 1922. The first published observation of hookworm in Palestine was made by Muhlens in 1913, but the case was not an indigenous infection, it was imported from America. Dr. Goldberg observed four or five cases among Arabs during 1912 and 1914, but the origin of the infection was not determined. It has been the intention of the author to investigate the existence of endemicity of hookworm disease in Palestine. Petach-Tikvah was the colony chosen for investigation, being the largest (5,000 inhabitants) and also because the inhabitants had for a longer period than any other colony engaged in the intensive cultivation of oranges, which require continual artificial irrigation. Results proved that Petach-Tikvah is an endemic centre of hookworm, a fact which has hitherto been overlooked, and cases which have occurred have possibly been misdiagnosed. Further investigations in 1924 confirmed those of 1922. The disease has probably been imported from Egypt, but the fact that large numbers of Indian and Egyptian soldiers were employed in Palestine during the war must be borne in mind. With the advance of agriculture, which will necessitate constant irrigation on a large scale, favourable conditions for the spread

of hookworm will be created in various parts of the country.

Blood-Serum Globulin in Leprosy (Chester N. Frazier and Hsien Wu).—The results in this series of cases indicate that Sia's globulin precipitation is positive in certain cases of leprosy, particularly in the nodular and mixed types of the disease. Of the thirty-two cases of leprosy on which this test was made seventeen of them were positive. The intensity of the reactions varied from one to three plus. In all of these cases the percentage of blood-serum globulin was estimated. The nodular cases showed an average of 4·68 per cent.; the mixed cases 4·52 per cent.; the active maculo-anæsthetic cases 4·23 per cent., and the latent maculo-anæsthetic cases an average of 3·11 per cent. The value of the test from a diagnostic point of view in the differentiation of kala-azar and schistosomiasis from leprosy is not of importance. Although the three diseases are often found endemic in the same regions, the clinical differences between the former diseases and leprosy are sufficiently distinct to prevent any confusion in their differential diagnosis.

It is impossible to see any relationship between the serum globulin content of the blood of the cases treated with the ethyl esters of chaulmoogra oil, and those not treated, sufficient to make it of any value as a clinical test for determining the efficacy of such treatment. It is suggested, however, that the blood-serum globulin and the precipitation test be studied in this relation to ascertain whether or not there is any decrease in the amount of serum globulin or the positiveness of the test parallel with clinical improvement. Although the serum globulin of leprosy does not reach the height it does in kala-azar and schistosomiasis, the total protein content exceeds that of these two diseases because of the behaviour of the serum albumin.

The Occurrence of Spirochæte-like Filaments in the Blood of Dengue Patients and in Normal Individuals (M. W. Hall).—Attention is recalled to the existence in the blood of motile filamentous elements, highly suggestive of living organisms. They occur in normal blood as well as in various pathological conditions. It is suggested that some at least of the forms described by Couvy and by Verwoort from dengue and allied fevers may well be of this type. Incidentally, the same may be said of the spirochætes described by Blanchard and Lefrou in the blood of blackwater fever. The use of the iron hæmatoxylin stain of Heidenhain after wet fixation in Bouin's fluid affords a means of distinguishing these spirals from true living organisms, although their differentiation from any forms known at present should not be difficult under the dark-field once the existence of these forms is taken into consideration. Some evidence has been adduced in support of the opinion that the platelets rather than the red cells are the main source of these filaments.

The Leprosy Problem in the Philippine Islands (G. R. Callender).—In this paper is pointed out the great amount of good done by the compulsory segregation of lepers in the Philippines. Compulsory segregation dates from 1906, when the leper colony at Culion was established. Prior to segregation cases of advanced and disfigured leprosy were frequently seen on the streets, even among labourers and employees in all occupations, to-day only those in the early stages of the disease are picked up. This latter fact attests to the value of segregation, but the desired result is still far from reached, and the Philippine Government is making extraordinary efforts to cure leprosy and determine the most efficient remedial methods towards this end.

The inauguration in 1921 by Governor-General L. Wood of the intensive treatment of all lepers segregated has been the largest experiment in the treatment of this disease, or any other, yet undertaken, and the excellent results obtained prove the value of this method. There is one condition in the colony at Culion with which the authorities thus far have been unable to cope, and that concerns the children of the lepers. It was attempted to separate the children from their infected parents, but it was found impossible, with the facilities available, to save the children.

Amœbic Abscess of the Liver (Ward J. MacNeal and Paul Klemperer).—A case is presented of amœbic dysentery with complicating liver abscess and fatal termination, fairly typical in clinical history and course, but which was not recognized until the autopsy. The disease was apparently contracted in New York City. From the ulcers the protozoa, *Endamœba dysenteriæ*, penetrated into the veins and were evidently transported through the blood-stream to the liver. Here an amœbic abscess was produced, which discharged amœbæ and eventually pus into the hepatic veins and the inferior vena cava to reach the lung capillaries through the pulmonary arteries. The bacterial infection was evidently secondary and of little importance until late in the disease. The authors suggest that for the identification of the parasites in unusual locations several staining methods should be employed to avoid mistake.

Mosquito Repellents (C. W. O. Bunker and A. D. Hirschfelder).—A systematic study has been made of a large series of definite organic compounds, to obtain data upon the relative repellent effects of a series embracing the simple hydro-carbons, the alcohols, aldehydes, ketones, ethers, esters and phenols, in order to determine whether repellent action is associated with the presence of any one definite organic radical or whether it is associated with any definite physical characteristic such as boiling point, &c. The experiments were made on the arms of human subjects, and at a time when mosquitoes were abundant. The results are tabulated; they certainly indicate a repellent effect of greater or less degree for most of the substances tested. To certain ones the mosquito would appear to be indifferent, if not actually attracted by them, for example, heptane, xylol, naphthalene, phenetol and benzyl benzoate.

Colonial Medical Reports.—No. 169.—Calcutta (*contd.*)

A coagulent is necessary—therefore alum is the one commonly used and has the formula— $Al_2(SO_4)_3$.

Alum combines with the alkali in the water forming $Al(OH)_3$, hydrate of alumina, a gelatinous substance which in falling entangles small particles in Group 1 and 2, making the proportion in Group 1, much larger and therefore hastening clarification by gravity settlement. But it has an important action on Group 3. A certain amount of alum, $Al_2(SO_4)_3$ probably becomes in water dissociated into hydrate of alumina and sulphuric acid. The result of this is that a large number of positively charged ions such as hydrogen and aluminium are freed and these neutralize the negative charges on the colloidal particles which then coalesce forming larger particles which are enmeshed by the aluminium hydrate already formed and therefore now fall into Group 2, and possibly Group 1, being deposited gradually by gravity. If sufficient alum is not added it is easily seen how the clarification will be incomplete, much of the colloidal matter remaining unacted on. Alum is the most commonly used substance for the purpose of dealing with colloidal matter; and is probably as effective as any yet known. More work on these electric colloids derived from clay is required to find some cheap practical and effective method of neutralizing their charges and depositing the particles. To form the hydrate of alumina, alkali in the water is required. I think it has been found that there is unusually enough alkalinity in the Hooghly water to act with the amount of alum necessary for clarification; I have not found that the addition of small quantities of lime is of any assistance in clarification of Hooghly water by alum. Further, if the settlement arrangements are not sufficient or are faulty, the water passing into the filter beds will not be sufficiently clarified. It is a well-known fact that slow sand filter beds cannot deal effectively with turbid water, the deposited mud interfering with the straining powers of the filterng layer. If there is much colloidal matter in a water we know that simultaneously the amount of particles of Group 2 will also be much increased. If the settlement is not satisfactory these Group 2 particles pass over on to the sand filter which will then not act as efficiently as before, possibly allowing more bacteria to pass through.

The following conclusions may therefore be stated:—

(1) The presence of colloidal matter derived from clay sources in a filtered water is not of itself harmful.

(2) Its presence in a filtered water, however, may indicate:—

(a) That sufficient alum is not being added to produce coagulation and clarification.

(b) That the increase in the amount of fine suspended matter (Group 2) may possibly not have been dealt with efficiently by coagulation and sedimentation and the efficiency of the slow sand filter may have been reduced by this and consequently the bacterial quality of the water may have deteriorated. Whether this is so or not can be determined by any deterioration in the results of bacteriological examination.

During the first days when this particular quality of water was coming down it is possible that an insufficient quantity of alum was being added to the raw water. By courtesy of Dr. Crake and Mr. Wilson I was privileged to go round the Pulta Works. As Mr. Wilson has pointed out, the settlement arrangements are not quite satisfactory. The length of time allowed is probably not long enough and the mode of connection between the tanks is open to criticism. These connections produce noticeable swirls and eddies and, as pointed out above, these eddies and currents will undo in a few seconds all the good that has been done by hours of previous quiet settlement. A brief consideration of the source of this colloidal clay may help in the study of the problem.

The Ganges water up country in the United Provinces, for instance, in the rains, contains much suspended matter but a very small proportion is colloidal. On the other hand the waters of the rivers coming from the districts of Chota Nagpur in Behar and Orissa, when in flood, contain much colloidal clay brought from the hills. The source is probably the laterite deposits. At Burdwan, for instance, which draws its water supply from the Damodar River, the problem is a yearly one. There are other rivers, e.g., the Ojay, which comes from Behar and Orissa and flows into the Hooghly north of Burdwan. There is also a canal, I believe, connecting the Damodar and the Hooghly. The opalescent matter, then, comes from Chota Nagpur districts and not from up-country. If the Ganges, as a whole, is small and there is a big flood in Chota Nagpur only, the Behar and Orissa rivers will bring down large quantities of fine matter and will form a large bulk of the Hooghly water. This in a few days will arrive in Calcutta and give trouble. This is what happened this year. A big burst of the monsoon reached Chota Nagpur before it had become established further north, hence a large proportion of Hooghly water came from the Chota Nagpur districts. If the Ganges also, however, is in flood it dilutes these waters to such an extent that fine matter may become proportionately small in amount. Not only this, the Behar and Orissa waters in flood are softer waters than the Ganges flood water. It has been found that the harder the water in temporary hardness, the more quickly does suspended matter tend to fall and settle. The flood water of the Ganges therefore acts in a measure as a coagulant on the Behar and Orissa flood water. If, therefore, the upper Ganges is in flood we are less likely to have trouble with opalescence in Calcutta

The moral of this is that if we could get previous information of local floods in Chota Nagpur the Water Works Superintendent would be forewarned

and be ready to add additional alum as soon as the flood water from Chota Nagpur reached Pulta.

The Health Officer remarks as follows:—

I agree with Major Stewart as to the high velocities between tank and tank and have already pointed this out to the Committee. I think we must start chemical treatment before the break of the monsoon so as to have the tanks fully charged with alum ready to deal with the first red water coming down the river. Generally, I agree with the views.

Appendix "B."

Analyst's report on the bacteriological examination of samples of water taken from the points where the effluents of septic tanks are discharged.

In the month of July it was observed that in addition to the presence of slight opalescence in the physical appearance of the filtered water the bacteriological quality of the same had deteriorated to a certain extent in as much as lactose fermenters, which are usually found to be absent in 10 c.c., were found to be present. This lead to a certain amount of uneasiness in the public mind, and a question was raised in the General Committee if this was to be accounted for by inefficiency of the filter beds or by discharge into the Hooghly in the vicinity of Pulta intake of septic tank effluents of high bacterial content and insufficiently sterilized. As regards the filter beds it is to be observed that the sudden influx of a large volume of flood water during the latter part of June, carrying with it an unusual amount of suspended and colloidal matter put a severe strain on the filters, but judging from the reduction in the number of bacteria they were found to be working fairly satisfactorily. As regards the question of the quality of raw river water it was resolved by the General Committee on July 20 that a survey of the river might be made in this vicinity of our Pulta intake and I was selected for the work. The Director of Public Health, Bengal, was approached who very kindly not only put a motor launch immediately at our service for collection of samples but also deputed Rai Sahib V. Gobinda Raju, Assistant Bacteriologist, Public Health Laboratory, to help me in the work. I take this opportunity to acknowledge that had it not been for the ready and valuable help offered by Mr. Raju, who is thoroughly familiar with this part of the river, it would have been impossible for me to perform this work within so short a space of time.

Between July 25, 1922, and September 2, 1922, altogether 100 samples have been collected from the river from Shamnagore on the north to Khardah on the south. The procedure adopted was to collect the samples in sets of three, viz., the shore in the vicinity of the discharge pipe of the septic tang effluents, the middle of the stream and the opposite shore. A few samples were taken near the Pulta intake. A few samples of septic tank effluents were also collected.

The samples may be broadly divided into four groups.

I.—Midstream, where the water is generally good and may be taken as control.

II.—Shore or Bathing Ghat, within 400 feet from the place where septic tank effluents are discharged.

III.—Effluents from individual septic tanks.

IV.—Samples from the river close to open drains receiving effluents from groups of septic tanks.

In the bacteriological results the presence of *B. coli* and its number in 1 c.c. have been taken as the standard for expressing the existence of fæcal contamination and its amount. Sir A. Houston, Director of Water Examination, Metropolitan Water Board, says "The *B. coli* test stands to-day as the most practical and delicate and rapid test for excremental filth and may surely be taken as the most reliable indicator in its positive aspects of possible danger and in its negative aspect of its almost certain absence of micro-organisms associated with epidemic water-borne diseases and generally speaking as the one test which above all others it is least excusable for a water analyst to omit."

It is to be noted here that the samples have been collected in the month of August, when the river was very full, and the volume of water in the river very large. The number of samples taken is also not sufficiently large to form a definite conclusion, but the following tentative conclusions may be drawn from the facts already obtained—

(1) The midstream water is much purer than water on either shores, as many as 16 per cent. of the samples showing one fæcal bacillus in 1 c.c., whereas in the shore samples none of them reached this standard of purity

(2) The shore samples are decidedly inferior in quality to the midstream ones, indicating that the amount of fæcal pollution near the banks is appreciable in amount.

(3) The Pulta intake water is decidedly superior to the other shore waters at this time of the year, but it is not possible to state at present what the condition would be when the volume of water goes down considerably as in January or May.

(4) Of the septic tank effluents examined none of them showed less than 100 fæcal bacilli in 1 c.c. and as many as 58 per cent. of the samples showed at least 100,000 fæcal bacilli per c.c. and 8 per cent. 1,000,000 per c.c., which is practically of the same quality as crude human fæces.

(5) The effluents of the Titagur Paper Mills which were mixed with the waste hypochlorate liquor and in which the smell of chlorine was markedly present, showed the absence of fæcal bacilli even in 10 c.c. in one sample, and in 1 c.c. in three samples, and in only one sample ten fæcal bacilli were present per c.c.

This shows that it is quite possible to sterilize the effluents if only a sufficient quantity of bleaching powder is used for the purpose.

(6) The water of the Titagar Khal, which receives effluents from septic tanks and which flows into the Hooghly about two miles south of Pulta intake shows a high degree of fæcal contamination

14 per cent. of the samples showing 10,000 fæcal bacilli per c.c.

(7) The Kharda Khal water, which also receives effluents from several septic tanks and flows into the river a little further south of Titaghur shows a still higher degree of fæcal pollution, of 33 per cent. of the samples showing 100,000 *B. coli* per c.c. and 16 per cent. 1,000,000 per c.c.

(8) Ichapur Khal water, in contrast to Titaghur and Khardah Khal waters, is decidedly superior. I understand it does not receive any septic tank effluent of any jute mill.

But I must say here that the number of samples is rather small and taken during the height of the rains. To arrive at a proper conclusion it would be necessary to collect further data and also at other times of the year, say in January, at the height of the cold season, and in May, the driest part of the year.

I give below an extract from Rule 19 of the Bengal Factory Rules, published under Bengal Government Notification No. 953 T.G., dated June 24, 1912.

19 (viii) The effluent from a septic tank latrine installation shall not be discharged into any river unless—

(*a*) it is clear, free from fæcal odour and non-putrescible, and nitrification has definitely commenced, and

(*b*) it has been sterilized by the addition to each gallon of 5 grs. of fresh chlorinated lime.

Appendix "C."

The Analyst's report on special circumstances under which commercial ghee is manufactured in Gontour, Madras.

Part I.

In accordance with the resolution of the General Committee, dated June 30, 1921, recommending my deputation to Madras to study local conditions there and to investigate the special circumstances under which commercial ghee is manufactured there, I left Calcutta on October 2, 1921, and went to Gontour, from whence practically all consignments of Madras ghee come.

I stopped at Gontour and used to spend almost the whole day in visiting the following villages within a radius of eight miles from the town itself, viz., Kortepadu, Yetkuru, Gourantla, Nullapadu, Potur and Kakani. The principal contention of the dealers has been that in Madras ghee is manufactured from a mixture of milk of cows, buffaloes, sheep and goats, in which cows' milk predominates. I state briefly the conditions which I observed in the different villages.

(1) *Kortepadu.*—A village within two miles north of Gontour; here I came across a very large number of buffaloes and comparatively few cows. One, K. Keteswara Rao, a schoolmaster in the village, gave me the following figures—buffaloes 400, cows 40. He also made the following written statement:—

> "The people who keep goats are called *Gollas*. They keep them chiefly for getting manure and the milk is used for drinking purposes, and not generally used for making ghee."

Sheep and goats are not kept in this village.

I took some samples of buffaloes' and cows' milk and made ghee therefrom.

(2) *Yetkuru.*—A village about four miles south of Gontour. Here also I found the number of buffaloes to be very large and very few cows. One, Y. Sitaramayya, Kurnum, village accountant, made the following written statement:

> "I am a resident of Yetkuru, I know all villages within a radius of ten miles from here. I know that no ghee is manufactured from sheep or goats' milk. Ghee is manufactured from buffalo milk only; for instance, in this village there are about 400 buffaloes and only five or six cows—cows' milk is used for drinking only and if any ghee is manufactured from same it is sold separately at a higher rate, some villagers keep sheep and goats but they are used only for manuring fields, milk produced by them is small in quantity and is used generally for drinkng purposes. At Yetkuru there are no sheep or goats."

I purchased some samples of cows' and buffaloes' milk and also some butter.

(3) *Gourantla.*—About four miles to the north of Gontour. I counted the number of cows and buffaloes which I came across and found buffaloes 103 and cows 37. Of course, many cattle had gone to the jungle to graze, it being 10 o'clock. I found also some goats and sheep, about 15 in number.

One old villager told me that he had about 20 or 30 goats and sheep, but he could not supply any milk. He further told me that he receives money from the cultivators if he takes his flock to the fields for the excreta.

Another villager, Nagya, said that in the case of a cow in milk if there be a bull-calf they always let the calf have the whole milk, as bulls are more precious than cows and fetch Rs. 100 to 125 each.

As regards food, one Ketya said that the cattle graze in the jungles, they give only some rice dust.

Here I purchased some samples of cows' and buffaloes' milk for the purpose of making ghee.

(4) *Nullapadu.*—A village about four miles west of Gontour. Here also I found a very large number of buffaloes and very few cows. A very old man, Gobinda Reddi, told me that there were about 200 buffaloes and 50 cows there. In this village about 13 families keep sheep and goats, the total number of the latter being about 1,500. On inquiry, I understand that goats and sheep are kept by a separate class of people who are called *Dhangirs*, who are a low caste and are not allowed to mix with the general villagers. They don't keep cows or buffaloes. One of them explained to me that

they keep goats and sheep for the following purposes:—

(*a*) On receipt of money they allow these animals to graze in the fields and thus manure them.

(*b*) The milk produced is used by them and excess is made into butter and ghee.

(*c*) The young ones are sold to the butchers.

I could not get any milk from them though I tried. I purchased some cows' and buffaloes' milk for making ghee.

(5) *Potur.*—A village about six miles to the north-west of Gontour.

In this village about 200 families live, most of whom keep milch cattle. There are altogether about 200 buffaloes and 15 to 20 cows. Here a group of *Dhangirs*, about 35 in number, live, having about 1,500 sheep and goats.

I purchased some cows' and buffaloes' milk, and also some goats' milk for the purpose of making ghee.

(6) *Kakani.*—A village about six miles to the east of Gontour.

Here I counted the cows and buffaloes I came across (44 buffaloes and nine cows). As many cattle had gone out to graze I was told that the total number would be about 200. A group of *Dhangirs* live here. The total number of goats and sheep would be about 1,200.

A respectable resident of the village, Sella Nagaya, merchant, made the following written statement in Telugu, which I have had translated, "A sheep gives about six tolas of milk, very little butter is produced. Sheep are chiefly used for manuring purposes (dung)."

The samples of milk which I collected at various places were brought to my quarters and ghee made in accordance with the process adopted by the villagers. The samples were all brought down to Calcutta and analysed.

I saw the Chairman of the Gontour Municipality, the Deputy Director of Agriculture and the District Medical Officer.

PART II.

Breed of cattle—Cows.—I cannot do better than quote the following from "Cattle of Southern India," by Lieut.-Col. W. D. Gunn, *re* cows:—

"The cattle of the Madras Presidency have long been famous, and of the several breeds which are to be found in this part of the country, those designated the 'Mysore' and 'Ongolo,' sometimes also known as the 'Nellore,' are undoubtedly pre-eminent.

"The Nellore breed of cattle has a wide reputation throughout India, and even beyond its limits. Formerly the normal breeding localities were situated within the northern taluks of the Nellore District of the Madras Presidency but recently these taluks have been included in the new district of Gontour, so the cattle should not rightly be given the name of Nellore, but rather that of Ongole, from which tract the best specimens can be obtained."—(Page 26.)

Page 28.—"There is no greater truism than that which refers to the necessity of feeding young stock; and the very great care which the best breeders bestow on the young animals, both male and female, most certainly accounts for the well-deserved reputation of the Ongole cattle. The young calves are allowed to suckle the whole of the cows' milk, and when they are three months old are given grass and a small amount of mixed grains. In every way they are treated and tended as the family pets."

Page 29.—"A good Nellore cow gives from 11 to 12 pounds of milk daily. Young bulls sell from Rs. 80 to Rs. 250. A good Nellore cow is worth from Rs. 80 to Rs. 150, according to the amount of milk she yields."

Re Buffaloes.—I make the following extract from the same authority.

Page 50.—"In Southern India there are probably four distinct varieties, viz., the Toda, which are found on the plateau of the Nilgiri Hills, the Parlakamede on the Ganjam Hills on the east coast, the Malabar, the best of which are to be found in the south-western portion of that district and South Canara, and the *small nondescript variety* which may be seen everywhere."

Now, in Gontour and the surrounding villages, though in a few instances I have come across buffaloes of good breed, most of the animals there belong to the aforesaid *nondescript variety*, and the degeneration is evidently due to indiscriminate breeding. In size and in disposition they are just like the country cows found in Bengal.

The usual yield of milk of a buffalo is about four seers, the usual yield of a cow is about four to six seers. The price of a buffalo is about Rs. 40 to Rs. 60 whereas that of a cow is Rs. 80 to Rs. 90. The price of pure buffalo milk is As. 5 a seer, that of cows' milk As. 6 a seer.

Food.—The Deputy Director of Agriculture says: "Cattle are mostly fed in these parts on paddy Juar and Bajri straw in addition to grazing and green grass when available. Milch cattle get gingelly cake, cotton seed and rice bron in the neighbourhood of the towns, but in villages they are kept only on straw and grazing." My experience has also been the same. In the interior villages poor people cannot afford to give oil cake, but depend only on grazing in the jungles.

Manufacture of Ghee.—This is well described in the Year Book, 1919, of the Madras Agricultural Department (page 75):—

"Milk, preferably buffaloes', is boiled on an open fire, the chief fuel used being dry cow-dung cakes. These are preferred in virtue of their slow burning quality, a quality essental in milk boiling. A mud pot is the common utensil for such a purpose, which is covered with another mud pot when milk is boiled. During boiling the smoke freely permeates through the milk which gives the milk and curd the characteristic smell with which all are familiar. The milk is then allowed to cool for a while after it is first brought to the boil, when a small quantity of the previous day's curd is added to sour it. It is then laid aside till next morning."

Colonial Medical Reports.—No. 169.—Calcutta (*contd.*)

The whole curd is then churned with the Indian beater churn. When butter has formed and floats on the top it is gathered by hand, made into a ball, slightly washed on the outside and preserved along with the previous day's lot. When a sufficient quantity of butter has accumulated it is melted over an open fire; I have noticed that the temperature rises to 120° to 130° C.; curd present in the butter probably gives aroma to the ghee and at the same time leaves a sediment. When all the water is evaporated, and the characteristic sound of bubbling ceases, the ghee is then strained through a cloth and is ready for the market.

Collection.—The quantity manufactured by an individual villager is small and he lives miles away from the town. There is a separate class of men, the Hindus being called Kumti or Bakal, and the Mohammedans, Sahiblu, whose occupation is to visit the distant villages, collect the ghee, pack it in tins and bring it in large quantities to the exporting towns. Here it is sold in the public market and the wholesale dealers, after satisfying themselves by physical examination, purchase it and store it in the godowns of the commission agents or Aratdars, who advance them money on the security of these goods.

Special treatment of Ghee at the Arats.—At the godowns of the Aratdars or commission agents, there are big cauldrons of 40 to 50 maunds capacity where tins of ghee as they come from the mofussil are mixed, melted by the application of direct fire and re-tinned ready for export. I have noticed that the temperature of the ghee in the cauldron varies from 90° to 105° C. It is alleged, and it is to a certain extent true, that the ghee as it comes from the mofussil is not properly made as it contains a certain amount of moisture and casein, which changes the physical characters of the different consignments to a certain extent. Impurities like mud, dirt, &c., are also found to be present. The idea of mixing and melting the ghee in a big vessel is to get rid of these imperfections and to reduce the ghee to a uniform quality. But I am afraid this process at the same time gives great facilities for adulteration to those who are so inclined—I am credibly informed by local people there, both official and non-official, that many of the dealers, if not all, extensively practise adulteration at the time of melting the ghee in the cauldron, unhindered and unchecked. The local municipality has neither the legal powers nor the agency to check this wholesale adulteration. The District Medical and Sanitary Officer has got certain powers but he has various important duties to perform, being in charge of a big hospital there. The unscrupulous dealers thus went on with their nefarious practices without any hindrance till they got a rude check from Calcutta. The famous case of Corporation v. Grande Venkata Ratnam which cost the defendant nearly Rs. 40,000 (I was told by the defendant himself) made a tremendous sensation; and the decision of the case in favour of the Corporation and the vindication of the Corporation figures in the face of the opinions of European experts not only saved the situation but also struck terror into the hearts of the unscrupulous —Madras ghee fell into disrepute, the price went down, and it attracted few customers. But I am glad to say that many of them have since changed their tactics, I have noticed that some of them at least try their best with the resources at their command to secure the best ghee possible. The effect of this is very noticeable in the Calcutta market, where in 1921 the proportion of adulterated samples in Madras ghee is very small in comparison with previous years. But though most of the consignments from Gontour come to Calcutta, some at least go to other places and a really effective check can only be effected at the place of production.

CONCLUSIONS.

1. The principal contention of the dealers in Madras ghee that commercial ghee there is manufactured from a mixture of milk of cow, buffalo, sheep and goats is baseless. The chief source of ghee supply is the milk of buffaloes. Cows' milk and cows' ghee are dearer. Sheep and goats are kept by a separate class of people (*Dhangirs*) for manuring fields and for meat. The Deputy Director of Agriculture confirms my experience.

2. Buffaloes in Gontour do not generally belong to any of the well-known varieties found in Southern India, though a few are to be found. Those usually kept by villagers belong to the "nondescript variety"—a product of indiscriminate breeding. In size, habits and temper they resemble the country cows of Bengal, the yield of milk is also similar, viz., two to four seers, and the price of an animal is less than that of a cow. The cows belong to the beautiful "Ongole" breed and are very much prized—the bulls are highly valued and are used for draught purposes and for ploughing fields. They sell at a higher price than buffaloes.

3. From the small number of analyses performed it is not possible to form an opnion as to any special features possessed by Gontour ghee. It is indeed true that some individual samples have given results that are lower than any we have hitherto received, and it is quite possible that the poor condition of the cattle, which in most cases pick up what they can grazing in the jungle, and the practical absence of any fodder in the fields at this time of the year (the rainy season begins here in the middle of October) may account for these results. But at the same time it is to be noted that the yield of milk from individual milch cattle in the district is very small, whilst commercial ghee is a mixture of the products of a very large number of animals, which varies within very narrow limits from the average, and tends to eliminate abnormal results. It will also be apparent from the results of analysis that samples taken from mixtures of several tins almost always give figures of 28·0 c.c., and above. Even if it be conceded that ghee from villages far from the towns is inferior in quality compared with ghee from other parts of India, where more care

is given to the food of the cattle, that is no reason why we in Calcutta should allow such inferior stuff to be sold in our markets. In my opinion we should insist on their complying with our standard of 28·0 c.c. As a matter of fact practically all good commercial samples of Gontour ghee will pass this standard.

I may further observe that if the standard be lowered to meet some of the abnormal samples of Gontour ghee it will neither be fair to dealers in ghee from other parts of India nor to the public of Calcutta, as it will allow a considerable quantity of adulterated ghee to escape detection.

T. K. GHOSE.

Health Officer's opinion:—

"I have read the very interesting report submitted by the Analyst and have discussed it with him. I agree generally with the conclusions he has arrived at. I certainly see no reasons for modifying our standards of purity."

H. M. CRAKE.

Colonial Medical Reports.—No. 170.—Trinidad and Tobago.

ADMINISTRATION REPORT OF THE SURGEON-GENERAL FOR THE YEAR 1923.

I HAVE the honour to submit for the information of His Excellency the Governor and the Legislative Council the following report of the medical department for the year ended December 31, 1923.

FINANCIAL.

Provision was made as per revised estimates for 1923, for the requirements of the medical department under head twenty-two, medical, for the sum of £31,943 16s. 3d., of which £30,291 16s. 3d. was actually expended, and a saving of £1,652 effected.

The amount provided under head 23, "Hospitals, Asylums and Dispensaries" was £100,890 18s. 11d which includes a supplemental vote of £896 for the purchase of a new launch for the use at the Chacachacare Leper Settlement, on which there was an actual saving of £4,881 14s. 1d., the actual expenditure being £96,009 4s. 10d.

Under heading "Public Health" including quarantine, provision was made for £17,124 17s. 9d., of which £16,290 1s. 10d. was actually spent, and a saving effected of £834 15s. 11d.

The total savings on the various votes controlled by this department was £7,369 10s. 0d., of which £530 15s. 1d. was contributed by the ankylostomiasis campaign vote.

The average annual cost per bed at the twelve Government Medical Institutions was £49 16s. 2d., as compared with £52 11s. 1½d. in 1922 and £55 4s. 8½d. in 1921, while the cost per bed per diem was 2s. 8d., as compared with 2s. 10½d., in 1922 and 3s. in 1921.

The revenue credited to the various medical institutions during the year was £4,682 19s. 6½d., as compared with £4,030 18s. 9½d. in 1922.

MEDICAL ATTENDANCE ON THE POOR.

The number of applications in Port-of-Spain during 1923 was 22,557, as compared with 25,942 in 1922, while the figure for the whole Colony was 58,530, as compared with 57,636 in 1922.

VENEREAL CLINICS.

The clinics established in Port-of-Spain and San Fernando continue to be highly appreciated by the general public.

RECOMMENDATIONS.

(*a*) The provision of a residential nursing home at the Colonial Hospital, Port-of-Spain.

(*b*) The completion of the nursing home at the Colonial Hospital, San Fernando.

(*c*) The appointment of a whole time medical officer for Chacachacare Settlement.

(*d*) The provision of a motor ambulance for Tobago.

K. S. WISE.
Surgeon-General.

HOUSE OF REFUGE, 1923.

I have the honour to submit for your information the annual report for the House of Refuge for 1923.

The general accommodation of the institution is satisfactory.

The staff numbers thirty-seven.

There is no housing accommodation for the staff save the resident superintendent, who is provided with quarters, and the steward who gets rent allowance and resides away from the institution.

During the year the following changes amongst the staff took place: Nurse Stewart resigned in March, 1923, and was replaced by Nurse Parris; Wardsman J. C. Jackman was dismissed, he having been charged by the police with wounding and sentenced to imprisonment and was succeeded by V. Marshall.

The buildings are in a dilapidated condition and require immediate repairs.

The grounds are in a fairly good condition, but some of the roads require a little gravelling.

The water supply is good and sufficient. Some

of the drains require repairs. The pail system is still in use and the latrines require some repairs to make them fly-proof.

The dietary is good and sufficient.

The accommodation for the patients is satisfactory and they all seem contented.

R. McLEAN.
Medical Superintendent.

COLONIAL HOSPITAL, 1923.

I have the honour to submit the following report of the Colonial Hospital, Port-of-Spain, for the year ending December 31, 1923.

Administration.

The extern maternity department has been doing good work during the year and has proved a most useful as well as efficient adjunct to the Victoria Maternity Ward in Hospital, whither the difficult cases are transferred by the district midwives.

Number of cases treated outside by district nurses ...	287
Number transferred to hospital requiring special obstetric skill	85
Number of visits paid by district nurses to midwifery patients at their homes	2,810

Anti-typhoid inoculations were started at the surgery of the Colonial Hospital on October 19, 1923, and 948 people have availed themselves of this facility.

The Princess Mary Medals for nursing were awarded for the first time this year and have proved to be a valuable incentive to keen and efficient competition among the nurses of the Colonial hospitals, Port-of-Spain, and San Fernando.

The sucessful candidates, Nurses Anderson (gold medallist) and Sealey (silver medallist), were presented with their medals at a special ceremony held at the Town Hall, Port-of-Spain, on November 8, 1923, which was largely attended, and I take this opportunity of expressing thanks in the name of the nursing staff of this institution to the mayor and councillors of the city of Port-of-Spain for the kind thoughtfulness and the noble ideals which have prompted the award of these medals. It is now left to the nurses of the Colony to live up to these ideals, and I have no doubt that they will do so.

The usual bi-yearly examinations for nurses in training were held in July and December. There were thirty-seven entrants from this institution, of whom thirty-one passed and six failed.

Buildings and Grounds.

Minor repairs to the various wards have been carried out. With a view to economy, no extensive alterations have been made except the screening of the northern and eastern side of the Tuberculosis Ward, which was too exposed to the weather.

Some necessary improvements in the kitchen and laundry have been unavoidably postponed.

No. 11 Ward, which is used for chronic male cases, is dilapidated beyond repair. Instead of building a new ward at the hospital for these cases, I consider it would be preferable to make provision for their accommodation at the House of Refuge.

The grounds are in fairly good condition.

Water Supply and Sanitary Arrangements.

The water supply has been ample and of good quality.

The sanitary arrangements are up-to-date and kept in good repair.

Dietary.

The diet scale continues on the whole to give satisfaction. A few minor additions and improvements are now being introduced, the most important of these being the substitution of fresh milk for condensed milk for practically all hospital cases.

Accommodation.

The authorized number of beds in the institution is 340. The chronic wards are usually overcrowded, due to cases which belong to the House of Refuge class having to be kept in hospital owing to lack of accommodation elsewhere.

Greatest number of patients in hospital on any one day	388
Lowest ,, ,, ,, ,,	284
Average ,, ,, ,, daily ...	336

During 1923 the number of in-patients treated at hospital was 5,849. Of these 4,697 were discharged and 834 died.

The high mortality is mainly due to the frequency with which patients were admitted in a very advanced stage of their disease and to the many advanced cases of pulmonary tuberculosis and senile cases that are permanently accommodated at this institution.

The number of casualties treated in the surgery, exclusive of in-patients, was 2,780.

Diseases.

The chief diseases treated were as follows:

Diseases	Number of cases	Number of deaths
Venereal diseases	328 ...	33
Pulmonary tuberculosis	307 ...	170
Enteric fever...	240 ..	45
Malaria	199 ...	18
Chronic nephritis	185 ..	75
Bronchitis (acute and chronic) ...	174 ...	26
Ulcers	166 ...	—
Dysentery and diarrhœa	129 ...	22
Lobar pneumonia	128 ...	57
Ankylostomiasis	113 ...	14

Surgical Operations.

A separate return of surgical operations is attached. There were 1,652 major operations performed during the year.

R. C. WUPPERMAN,
Resident Surgeon.

SAN FERNANDO HOSPITAL, 1923.

I have the honour to submit the following report on the Colonial Hospital, San Fernando, for the year ended December 31, 1923.

The midwifery examination was held at Port-of-Spain in August. There were four candidates from San Fernando Hospital, two passed.

The nurses' examination was held at Port-of-Spain in December. There were twenty candidates from San Fernando Hospital, eight third year, six second year and six first year; of these five third year, four second year, and six first year candidates passed.

Throughout the year the medical staff consisted of only two medical officers. It is impossible to emphasize too much the need for a third medical officer. The work would be very much facilitated by the appointment of a permanent senior assistant.

Quarters were provided for the resident surgeon, assistant resident surgeon, matron and dispenser.

Buildings.

The female wards and maternity ward are in good condition. The male wards are in bad condition and in need of repairs and painting. The central block, containing the surgery, offices, dispensary, and matron's and dispenser's quarters, is also in need of repairs and painting. Work in the kitchen was performed under difficulties throughout the year, on account of the bad condition of the kitchen range.

The Public Works Department handed over the first wing of the Nurses' Home in March. In April a retaining wall was built to the west of the hospital grounds to secure the Tuberculosis Ward: the old laundry was demolished and a new one built on a site south of the former one. Both operating theatres were painted in December.

The resident surgeon's house is in very bad condition. Extensive repairs are necessary and also a new fence.

The condition of the assistant resident surgeon's house is unsatisfactory, owing to the shifting nature of the land on which it is built.

Grounds.

The hospital grounds are not enclosed, a proper fence completely enclosing the grounds is required. The roads in the grounds are in need of constant attention, this would be overcome by having them properly conditioned and oiled. The paths connecting the different buildings are neither paved nor oiled, and so with the amount of traffic that must go on in and out of the wards, it is impossible to keep the floors as clean as they should be, especially in the rainy season.

A small flower garden was maintained and the kitchen garden yielded some return.

The retaining wall recently built to secure the Tuberculosis Ward is bulging and cracked; this requires immediate attention.

Water.

The water supply was ample and good.

Sanitary Arrangements.

These are unsatisfactory. The installation of a modern sewerage system is urgently required. The drainage can be improved.

Dietary.

The diet is satisfactory and the cooking good. The meals, however, are served very irregularly owing to the bad condition of the kitchen range and the consequent difficulty in getting the food cooked in time.

Accommodation.

Accommodation is provided for 153 patients. Twenty beds are reserved for cases of tuberculosis and seven for difficult midwifery cases. There are three rooms for private patients.

Seventy patients were admitted to the Maternity Ward for treatment. The extern midwives attended to 81 cases; they made 731 visits.

There were 347 deaths in the hospital.

Venereal Clinic.

This was opened daily for the treatment of patients. 100 cases of gonorrhœa and 233 cases of syphilis were treated. 801 injections of neo-salvarsan were given and forty-nine injections of mercury, *i.e.*, each syphilitic patient got an average of 3·5 injections of neo-salvarsan and 0·2 injections of mercury. This is very unsatisfactory as under such conditions a very low percentage of possible cures can be obtained. The assistant resident surgeon attends at the clinic on Wednesdays and Saturdays.

The chief diseases treated were:

Disease	Number of cases	Number of deaths
Ankylostomiasis	172	29
Venereal	153	3
Malaria	152	12
Bronchitis	102	7
Pneumonia	101	29
Phthisis	71	36

J. E. A. BOUCAUD,
Resident Surgeon.

LUNATIC ASYLUM, 1923.

I have the honour to submit the annual report on the working of this institution during the year ended December 31, 1923.

ADMISSIONS, RECOVERIES, DEATHS.

The admissons, which exceeded those of the previous year by thirty-three, the increase being equally distributed among males and females, were still below the average of the preceding quinquennial period: "Mental anxiety" and "Adverse circumstances" were assigned more frequently than usual as the exciting causes of the mental attack. Hereditary predisposition was obvious or ascertainable in fifty per cent. of the admissions.

Only nine of the admissions improved sufficiently to be discharged within the year, the average stay in asylum of those discharged on recovery being over three years. The benefit of prolonged detention under institutional treatment is, however, well reflected in the low percentage (eight per cent.) of re-admissions to this asylum.

Colonial Medical Reports.—No. 170.—Trinidad and Tobago (*contd.*)

The number of deaths (eighty-six) slightly exceeded that of 1922, but was also below the average of the preceding quinquennial period. Thirteen of the deaths were of inmates between sixty and eighty years of age. Tuberculosis caused eighteen deaths.

The ratio of certified insane to population in the Colony is now just under 20 per 10,000. (In Great Britain the ratio is about 30 per 10,000.)

Accommodation.

There were at the end of the year under review forty-one vacancies for males and seventeen for females—a welcome postponement of overcrowding. The total number under treatment was 795

Buildings, Water Supply.

The buildings are in good order. The water supply proved ample. " Foamite " hand fire extinguishers were installed in those officers' quarters which were beyond the reach of the fire hydrants.

Employment.

The extension of ground cultivation and of artisan work afforded throughout the year valuable employment and training for a large number of the inmates. The daily average number employed throughout the institution exceeded forty per cent. of the total number resident, while the value of the produce and of the labour of the inmates was over £3,000.

Health of the Institution.

Typhoid fever made its appearance among the inmates in August. Four females (one death) and three males were attacked. No definite focus of infection in the asylum could be traced. The disease was probably introduced in contaminated fruit and sweets brought in by visitors. The incidence of asylum dysentery was considerably less than in recent years.

GEO. A. VINCENT,
Medical Superintendent.

LEPER ASYLUM, 1923.

I have the honour to submit the following report for the year ending December 31, 1923.

The general accommodation of the institution is sufficient for staff and patients and the general health of the latter is well maintained.

The staff consists of two superintendents (one at Cocorite and the other at Chacachacare), a dispenser and a steward at Cocorite and a dispenser-steward at Chacachacare; all of whom are resident.

Added to the staff are twenty-three employees at Cocorite and eleven at Chacachacare. Cocorite has also seventeen sisters as resident nurses. The eleven employees at Chacachacare live on the Settlement.

The scale of diet approved by His Excellency the Governor on March 27, 1923, is satisfactory.

Cocorite.

During the year the services of three nurses, three warders, two watchmen, a cook, a baker and a laundress were dispensed with at Cocorite.

The wards require painting. The roofs of the wards covered with genasco, the galleries of Wards 2 and 4, and the room of the closet-attendant are in need of repair. On the whole, however, the buildings are in fairly good condition.

The water supply is ample and of good quality. The drainage and sanitary arrangements are good. The incinerator works well.

The gully which runs through the grounds of the asylum has to be cleared of debris periodically during the rainy season to prevent the flooding of the quarters of the resident superintendent and the nursing staff.

Christmas toys are distributed by Miss Pierre who with her co-workers and friends of the institution deserves our warmest thanks for the pleasure which their arduous work and generosity afforded.

The sisters carried on their work of mercy with the efficiency and patience that has continuously marked their efforts for the last fifty-five years, during which their religious house has been in charge of the Cocorite Asylum.

There are twelve wards which provide ample accommodation for the 300 patients now there.

Early in November there was an outbreak of diarrhœa. More than a third of the inmates (117) were attacked. With the valuable assistance of the sisters the disease was kept under control and there was only one death.

Nineteen Indians were repatriated in 1923.

Chacachacare Settlement.

The transfer of inmates to Chacachacare continued and sixty-nine patients were sent from Cocorite to the Settlement during the year. 157 lepers are now satisfactorily accommodated there (December 31, 1923).

Of the twenty-six cottages on the Settlement, ten were built in 1923. A good oven has been built and the supply of bread has been fully equal to the demand.

The supply of water has given rise to some anxiety but used with care has been sufficient for the needs of the patients.

The laundry work of the Settlement is done at Cocorite.

E. HAMEL SMITH,
Medical Superintendent

Colonial Medical Reports.—No. 171.—Mauritius.

ANNUAL REPORT ON THE MEDICAL AND HEALTH DEPARTMENT OF MAURITIUS FOR 1923.

Vital Statistics.

The area of the Mauritius is 720 square miles (460,800 acres) and the estimated population on December 31, 1923, was 381,678.

The density of population is very high, being about 530 per square mile for the whole island.

Births.—The total number of births for the year was 13,879.

Deaths.—During the year 1923 the total number of deaths was 10,778.

The mortality in 1923 was very low for Mauritius. The death rate for the whole colony is the *lowest since* 1891.

The number of deaths due to malaria and cachexia (highest death-producing factors in Mauritius) is 1,979.

No doubt can be attached to the improvement in the health conditions if it is remembered that in Port Louis no death is registered unless certified by a medical practitioner.

The number of deaths due to malaria in Port Louis in 1923 is 169.

It can therefore boldly be advanced that Mauritius is already remarkably deriving the benefit that was justly expected from the improved and energetic methods of public health campaign started three years ago and pushed on unremittingly.

The next high causes of death are: pneumonia and broncho-pneumonia (1,393 in 1923) and diseases of early infancy (1,026 in 1923).

Deaths due to preventable diseases, i.e., diseases due to faulty sanitary conditions, overcrowding, soil infection, defective or infective water supplies numbered 4,227.

This figure does not include infantile diarrhœa or infantile convulsions, both probably due to improper dieting and neglect.

Infantile Mortality.

It is a valuable index from the public health point of view and may be described as the index of community intelligence, for generally speaking it is found that the better educated and better housed sections of the community usually show lowest rates.

The rate for 1923 was 139·4 per cent.; the number of deaths under five years, 3,587.

Having regard to the total number of deaths for the year, viz., 10,778, the proportion of deaths under five to total deaths is so high as 33·3 per cent.

As usual, the most important cause of infantile mortality is congenital debility.

The number of still-births registered during 1923 is 1,557.

It is equivalent to 112·2 of live births for the same period.

The principal causative factors of infantile mortality continue to be: venereal diseases, congenital debility, premature birth, improper food and methods of feeding.

Many children on birth are mere weaklings and are doomed to early death owing to the early marriages amongst Indians and child-bearing at immature age, work of expectant mothers in the fields, hardships and privations in the poorer classes, apart from the main causes mentioned above.

These causes are *per se* sufficient to lead to death during the later months of gestation.

Infantile mortality is in every country usually higher among males than among females, except in the case of whooping-cough.

During 1923 the deaths under five years were 3,587.

Midwifery and Child Welfare.

During 1923 the questions of proper training of midwives and of placing gratuitously the services of Government paid midwives at the disposal of the poor in populous centres were thoroughly reconsidered.

Government proposes to provide Rs. 5,000 subsidy the next financial year to the dormant Midwifery and Child Welfare Society.

Prevalence of Sickness and Recurrence of Particular Diseases.

The number of cases treated in the public hospitals and at the dispensaries for 1923 is 82,326. These figures show a decrease as regards hospital admissions and dispensary cases

Malaria.

Malaria is not a notifiable disease in Mauritius so the number cannot be accurately given beyond admission for the disease in hospital, treatment at dispensaries and deaths certified by medical practitioners.

The total number of admissions in hospitals for malaria (hypertrophy of spleen included) was 1,774. The case mortality was 2·1 per cent.

The death-rate for malaria per thousand of population was 5·1.

The rates for deaths returned under malaria and malarial cachexia were 5·2 for 1923.

The admissions during the year under review were for malaria 1,558, deaths 35; admissions for hypertrophy of spleen 216, deaths 3.

In the public dispensaries a total of 19,268 cases of malaria were treated.

Spleen Examinations and Blood Tests for Malarial Parasites.

Spleen census of school children continues to be taken twice during the year.

The conclusion to be drawn from the examinations made in 1923 is a general decrease in the prevalence of malaria.

The total number of children examined is 12,925.

The examination of the blood of school children with a view to ascertaining the presence of malarial parasites has been carried on by a trained microscopist all the year round.

PNEUMONIA.—In the whole colony the total number of deaths is 1,083.

The admissions into hospitals were 287 with 103 deaths.

INFLUENZA.—In the whole colony the deaths stand at 556. The hospital returns show 1,192 admissions with 53 deaths. The hospital case mortality in 1923 was 4·4 per cent.

BRONCHITIS.—The total deaths registered in the colony numbered 521.

In this case the hospital admissions reached 925 with 23 deaths.

DYSENTERY.—Dysentery is not a notifiable disease in Mauritius. The mortality due to that disease in 1923 was 318. The hospital admissions show 379 with 24 deaths. The hospital case mortality was 6·3 per cent.

In the dispensaries 1,573 cases were treated.

ENTERIC FEVER.—In the whole island 150 cases were registered.

The months of particular prevalence were April and August.

Seventy-seven cases were treated in hospital.

The deaths (thirteen) gave a case mortality of seventeen per cent.

LEPROSY.—The number of inmates at St. Lazare Leper Asylum on January 1, 1923, was thirty-seven.

There were sixteen admissions during the year, two deaths and fourteen discharges. There remained thirty-seven lepers at the end of the year.

Leprosy is not a notifiable disease in Mauritius. It is probably common enough in the colony. Every day cases are met with in the streets of Port Louis and elsewhere. No restriction is made except as regards mendicant and criminal lepers.

No law exists for the compulsory segregation of lepers. Thy wander about at liberty, living with their families and transmitting the disease. There is no power to prohibit marriages between or with lepers, hence the hereditary taint continues to be spread.

The construction of the new (Powder Mills) Leper Asylum has been completed and the opening of the institution effected on January 1, 1924, by the transfer of the lepers.

In the draught Public Health Ordinance leprosy is made notifiable and the segregation of pauper, convict and vagrant lepers is rendered compulsory.

Treatment is given in the form of injections of moogrol. "Oscol" stibium has also been received in connection with leprosy treatment and with the opening of a new leper asylum under the management of another medical officer, the systematic treatments with moogrol and "oscol" stibium will be started in the near future.

PLAGUE.—The cost of the rat campaign works out for 1923 at fifty-one cents per rat caught.

In 1923 human plague prevailed practically all the year round in Port Louis.

Rat catching was persevered with throughout the year, and every rat caught, killed or found dead was examined bacteriologically.

During the year all grain stores were regularly and often fumigated by means of the Clayton apparatus.

METHOD OF TREATING CONTACTS.—(*a*) Disinfection—All premises, both of patients and of contacts were claytonized; (*b*) burning of rags; (*c*) isolation of patients as well as contacts *in situ* or in lazaret; (*d*) bathing of contacts; (*e*) inoculation by prophylactic vaccine.

DIPHTHERIA.—In the whole colony forty-seven cases were notified and five deaths registered. Five cases were treated in hospital with one death.

MEASLES.—This disease was made a quarantinable disease.

Nine cases were notified in December, 1923. No hospital admission.

CANCER OR MALIGNANT DISEASE.—Eighty-seven cases admitted into hospital with nine deaths.

DIARRHŒA AND ENTERITIS.—In the whole colony 625 deaths occurred. In the hospitals 506 cases were admitted resulting in forty-five deaths, giving a case mortality of 8·9 per cent.

ORGANIC DISEASES OF THE HEART.—Deaths from organic diseases of the heart numbered 151 in 1923. The number of cases admitted to hospital was 117 with twenty-two deaths.

VENEREAL DISEASES.—Twenty-two deaths were registered under syphilis in 1923. In hospitals 254 cases were treated. Five deaths resulted from these.

It is proposed to open the Venereal Clinic in the near future. As already stated, venereal disease is probably of more frequent occurrence than the above figures would otherwise denote. Most cases are concealed, a few treated by private medical practitioners, and only cases which incapacitate from work seek admission into hospitals.

NOTIFIABLE CONTAGIOUS AND INFECTIOUS DISEASES.—Ordinance No. 47 of 1898 provides for the compulsory notification of plague, cholera, choleraic diarrhœa, small-pox, yellow fever, diphtheria and membranous croup, measles, scarlatina or scarlet fever, and the fevers known by any of the following names: typhoid or enteric, typhus, relapsing or continued and puerperal; and traumatic erysipelas and of any other disease that may be added thereto by regulations. Cerebro-spinal meningitis has been made notifiable; so also the disease known as Spanish influenza.

CEREBRO-SPINAL MENINGITIS.—One case was notified; it ended fatally. Two other patients were

treated for the same disease during the year under review.

ERYSIPELAS.—Sixteen cases were notified and nine deaths registered.

Hospital admissions numbered twenty-four, resulting in four deaths.

SMALL-POX AND VACCINATION.—There has been no small-pox in the island since 1913. A total of 9,179 children were vaccinated during the year and 9,093 were successful vaccinations. In eleven cases the results could not be ascertained. In some cases vaccinations are privately performed, these are not included in the above figures.

PUERPERAL SEPTICÆMIA.—In the whole colony 228 women died in consequence of the puerperal state. Twenty-four cases of puerperal septicæmia were treated in hospitals, resulting in nine deaths —eighteen notifications were received during the year.

13,879 births having been registered during the year, the mortality among women in child-birth is 16·4 per thousand of live births, a very high figure.

ITCH (SCABIES).—154 cases were treated in the hospitals.

ANKYLOSTOMIASIS.—Fifty-one deaths were registered during the year. 500 cases were treated in the hospitals, with thirteen deaths.

BERI-BERI.—(Not notifiable).—Five deaths were registered in the whole colony.

Thirty-one cases were treated in the hospitals, resulting in two deaths.

PULMONARY TUBERCULOSIS.—Notification of pulmonary tuberculosis is not compulsory in Mauritius. In the new Health Ordinance the disease is made notifiable.

Hospital admission indicate a further decrease in the prevalence of the disease, 368 in 1923.

The mortality from pulmonary tuberculosis in the whole colony was 828.

CHICKEN-POX.—Five cases were treated in Beau Bassin Prison Hospital.

MENTAL DISEASES.—The total number of persons certified insane on December 1, 1923, was 708.

The causes of insanity are reported to be mental worry, grief, hysteria, fever, influenza, heredity, alcoholism, epilepsy, syphilis and gandia smoking.

Summarizing the experience of 1923, insanity caused by alcoholism, toxic mania, opium and gandia smoking appears to decrease whereas puerperality and hysteria have been factors bringing in the asylum more patients than usual.

Treatment with arseno benzol, bismuth, enesol has proved beneficial, so also has been the introduction of scopolamin and morphine in the treatment of excitement.

SOIL SANITATION.—The soil sanitation campaign has been pushed on very energetically during 1923. New regulations have been put into force regarding septic tanks, disposal of human excreta and trenching and manure factories, regarding the removal of house refuse, &c. New regulations have also been put into force relative to the provision of pail and pit latrines of approved type.

It is expected that soon every district will have been sanitated, i.e., every premises provided with an approved type of disposal of dejecta, viz.: septic tank, pail latrine or pit latrine.

ANTI-*MALARIAL* WORKS.—The work has consisted mainly in the maintenance of existing works, repairing of damage done by animals and floods, clearing of marshy lands, filling up of quarry pits and weedy pools and ponds, planting grass in former river or stream beds and petrolization of large marshes. The staff of trained moustiquiers did good work in the search of mosquito-breeding places all over the island.

THE CIVIL MEDICAL STORES.

The following tabular statement summarizes the transactions of the medical stores during the year 1923:

1.—Cost of drugs, chemicals, instruments and repairs to instruments and appliances, &c.	Rs.	103,601.80
2.—Value of drugs, chemicals, instruments, &c., issued to Government Institutions ...	Rs.	75,701.33
3.—Value of disinfectants, sera, vaccine &c., issued in connection with plague and other contagious diseases	Rs.	41,536.89
4.—Amount realized by sale of medicines, vaccine and sera to private medical practitioners and value recovered for loss and damage to instruments issued to Institutions	Rs.	1,755.70
5.—Quantity of Quinine issued		12,087 *oz.* 272 *grs.*
6.—Cost of Quinine issued ...	Rs.	22,735.14

7.—Institutions to which drugs in general are issued:

Hospitals	12	Schools	150
Dispensaries ...	31	Police Stations ...	54
Charitable Institutions	10	Govt. Institutions	15

The total number of notifications of infectious diseases (exclusive of plague) received during the year was 258.

The number of plague cases in the colony during the year 1923 was 139; the number of deaths 118.

DESTRUCTION OF RODENTS.

The number of rodents caught in Port Louis and country districts was 83,361.

29,223 were microscopically examined and the number found plague infected during the year was 568.

ABRIDGED REPORT ON THE WORK DONE FOR THE RELIEF AND CONTROL OF HOOKWORM DISEASE BY THE DEPARTMENT OF ANKYLOSTOMIASIS DURING THE YEAR 1923.

1. *Organization.*—During the year a great deal of time has been spent in propaganda.

On September 15, a branch office was opened in Moka, systematic work in the district was started and the year ended with the prospect of Moka being very soon completely sanitated.

Colonial Medical Reports.—No. 171.—Mauritius *(contd.)*

The schools were systematically examined and treated, and treatments were given in the branch dispensary, and the inhabitants were assembled at numerous centres for treatment.

2. *Extent of Operations.*—Although Moka is the only district where regular systematic intensive work has been attempted, the influence of the campaign has extended all over the island. Specimens have been received from all parts of the island, and there have been many requests for treatment or advice. These applications were from private individuals and also from public and private institutions. The local medical practitioners have very frequently referred their patients to the laboratory and a large number of treatments have been taken privately for hookworm and other intestinal parasites, which have not been within the scope of the control of the department and therefore not included in the statistics. A number of estates have also treated their own labour force, and numerous treatments have been given in Government dispensaries and hospitals throughout the island.

3. *Examinations, Treatments and Cures.*—The figures for examinations, treatments and cures during the year are as follows: Census 15,198, examined 12,540, infected 7,846, treated 5,506, cured 1,010. Both oil of chenopodium and carbon tetrachloride were used for treatment, the patients being administered either drug or a mixture of both.

4. *Infection with other Parasites.*—The number examined for hookworm disease was 12,540, of those incidentally found positive for ascaris 6,908, trichocephalus 8,294, strongyloides 11, oxyuris 22.

5. *Educational.*—Fifty-five lectures were delivered and literature distributed.

The cinema film "Unhooking the Hookworm" was ordered and delivery expected during the month of January.

6. *Per capita cost.*—The actual expenditure for the campaign during the year amounted to Rs. 29,702.16. Of this sum the International Health Board contributed Rs. 19,959.69, the Government's expenses being Rs. 8,742.47.

7. *Sanitation.*—The Medical and Health Department has expended a great deal of energy in trying to control and improve the sanitation, and regulations have been adopted dealing with trenching and the disposal of engrais. Unfortunately, it took a considerable length of time to accomplish results on account of existing contracts and local conditions.

1,698 pail latrines were completed by December 31, in Moka district, and the pail contents disposed of by deep trenching. In some sections pail latrines were built and in other places the pit was built where it would not pollute sub-soil water.

ANNUAL REPORT ON PORT LOUIS FOR THE YEAR 1923.

Vital Statistics.—The following figures for the town and district of Port Louis are taken from the report of the Honourable the Registrar-General: Population, 51,769; birth-rate, 39·9 per thousand; death-rate, 34·1 per thousand.

Reorganization of the Sanitary Staff.—A certain amount of reorganization and consolidation of the sanitary personnel was undertaken during the early part of the year.

The most important change was the extension of the responsibilities of the sanitary inspectors. The post of controlling officer was abolished, the plague services and anti-malaria gangs were reorganized so as to place them directly under the control of the sanitary inspectors who were thus given a more responsible, but at the same time a more stimulating share in the duties of the department.

Towards the end of the year the remainder of the anti-malaria work in the Port Louis district passed into the charge of the M.O.H. who thus assumed the responsibilty of all the sanitation of the district.

An important result of the reorganization referred to above was that provision could be made to reinforce the weaker branches by the creation of new posts out of the savings effected by the change. This was duly accomplished. The sanitary inspectors and guards welcomed the new arrangements and did their best to do their part in making it a success.

Class of Instruction.—While the reorganization was being worked out, the department's responsibility to the sanitary staff was fully recognized, and it was decided to hold classes of instruction which would help the personnel to a fuller appreciation of their duties. On April 12, the director inaugurated the class by delivering to the members a short and stirring address. The class, which is held every Thursday afternoon, is attended by all the sanitary personnel of the Northern districts.

The M.O.H., Port Louis, has delivered lectures on elementary physiology and hygiene, the epidemiology of the commoner communicable diseases, disposal of night-soil, and water supply; while sanitary inspector Purvis has given eight lectures on the elementary mathematics of hygiene. The programme of lectures has been based on the syllabus of subjects issued by the Royal Sanitary Institute and it is hoped that ultimately a certain number of candidates will be prepared to present themselves for the examination for the certificate of competency granted by the institute.

Communicable Diseases.

Three communicable diseases are of major importance in Port Louis: they are malaria, plague and enterica.

Anti-Malaria Work.—225,293 feet of existing drains and canalised streams were upkept. In addition, a small marsh at Grand River North West Village was drained into the river mouth. This marsh harboured the larvæ of *A. mauritianus* as well as those of *A. costalis*.

The clearance of a zone half a mile in depth in the Pitot and Tranquebar Valleys has continued

throughout the year. Until the end of September the work was carried out by the malaria authority. The object of the zone, which was recommended by Dr. Balfour, is to prevent the invasion of the city by mosquitoes coming from the jungle areas in the upper parts of the valleys. By the end of the year an area of 195 acres had been cleared of cactus and other rank vegetation in the locality. Unfortunately, it was not found to be possible to undertake work in the valleys themselves, only the Crown Lands on the adjacent hills having been dealt with. The work is carried out in three operations, cutting and stacking the cactus, allowing a period for desiccation and finally burning it as often as is necessary.

In the intra-urban area the anti-mosquito campaign has been steadily pursued throughout the year. Culex and stegomyia genera flourish in the town. The difficulties in the way of progress in eradicating their breeding places are enormous, and at times the situation seems to be almost hopeless. The profoundly dilapidated condition of the majority of the premises in the town is responsible for over half of these mosquito breeding places. Defective roof gutters, ill-paved yards, badly laid drains, ruinous masonry work, flooded cellars, to mention only a few, render the detection of such places difficult and their elimination tedious.

In addition to the above-mentioned genera, one Anopheline, *A. costalis*, is also to be found to some extent within the municipal boundary. This is partly due to the fact that there are many vacant plots and waste areas in the town so that some parts resemble open country with only occasional houses scattered over a comparatively wide area, while another reason is that the mosquito appears to have become, to some extent, domesticated, inasmuch as its larvæ are to be found somewhat widely distributed in the typically urban portions of the town, in odd pools, on paved drains and in other small collections of standing water.

Plague.—The septicæmic and pneumonic forms are almost always fatal. Cases of plague have been detected in Port Louis throughout the year, although the largest number of cases occurred during the hot weather.

Plague Prophylaxis.—As a routine prophylactic measure, mass inoculations with anti-plague vaccine were practised. The work done in this respect is summarized herewith.

Rat-proofing of houses was begun in November, and it is hoped that as the work progresses there will be a proportionate diminution in the number of plague-infected areas in the town.

Rat Fleas.—During November and December some sixty fleas were collected from Port Louis rats. With the exception of three defective specimens that could not be identified all of the insects resembled *Xenopsylla cheopis*. *X. astia* has not yet been encountered in Port Louis, but the work of collection and examination will be continued with a view to ascertaining whether *X. astia* exists here or not.

Twelve of the specimens were found in a wooden bin containing rice in a grocer's shop. Plague-infected rats had been found previously upon the premises which were fumigated by burning sulphur in open burners as a disinfestation measure after disinfection. When the premises were opened up after fumigation the fleas were found to be apparently unaffected by the gas, although roaches had been killed off in large numbers. It is possible that the gas had failed to penetrate the air spaces between the individual grains, which retained sufficient oxygen to tide the fleas over the period of fumigation, while the larger insects whose oxygen demands were presumably greater succumbed, even although they are notoriously more difficult to kill than fleas. Following upon this interesting observation, steps were immediately taken to revise the technique of fumigation by sulphur with a view to making it more effective.

Anti-Rat Campaign.—During the year 55,273 rodents were destroyed and submitted to microscopical examination for plague infection. 534 of the total number of rodents examined were found to harbour the *Bacillus pestis*.

The means taken for the destruction of rodents were: (*a*) poisoning by poisoned baits; (*b*) trapping in spring and cage traps; (*c*) trapping by means of "glue-boards."

The glue boards were employed originally at the suggestion of Dr. Balfour, and they have given such satisfaction that their use has been gradually extended. One great advantage of the glue board is that it captures a great proportion of the rat fleas as well as the rat itself and so limits the spread of infection. Owing to a temporary shortage of imported rat varnish, it was necessary to attempt to manufacture a substitute locally. After several experiments a very satisfactory lime was produced. The method of manufacture is as follows: heat two litres of boiled linseed oil, and when the oil has boiled for thirty minutes, add five kilos of powdered resin in small quantities, stirring all the time. The stirring and heating are continued for about half an hour, by which time the mixture should be of the required viscosity—as determined by trial. It is then ready for use.

Enteric Fever.—The figures, which include notifications under the term "continued fever" showing the incidence of fevers of the "enterica" group, throughout the year amount to fifty-eight cases, deaths nineteen.

It would be unduly optimistic to suppose that these figures give a true picture of the case incidence of the disease. It is almost certain that many mild cases escape notification on account of the fact that a qualified medical practitioner is seldom called in to see the patient, or, if he does happen to be summoned, is given little real opportunity to make a diagnosis of the malady.

It has been practically impossible to determine the origin of the cases. There has been no evidence brought forward to incriminate the milk supply. The detection of carriers will always be an unnecessarily difficult matter so long as there is an

absence of proper laboratory facilities in Port Louis itself.

In the absence of definite evidence to the contrary it has been thought that the water supply has been the medium of spread of the infection. An improvement in the quality of the water supply should therefore reduce the case incidence and the death-rate from this group of fevers. The "residual typhoid" will be then more easily investigated and with better prospect of success.

School Medical Inspections in Port Louis.

The principal diseases noticed were: pediculosis, scabies, skin diseases, defective eyesight, ear troubles, tonsils and adenoids, bad teeth, rickets, malaria, ankylostomiasis, schistosomiasis and other worm infection.

The number of pupils examined amounted to 4,498.

The figures show a decided improvement as regards the number of children affected with pediculosis, malaria, ankylostomiasis and other worm infections.

The number of children affected with ear troubles and inflammation of the tonsils has increased in a marked degree owing to the presence of influenza which prevailed during the second half-year. The number of children affected with scabies has also increased.

The figure for malaria shows, I am glad to say, a considerable decrease, this in spite of the heavy and continuous rainfall we have had during practically the whole period under review.

The figure for ankylostomiasis also shows a marked decrease, due very probably to the effective measures taken by Dr. Hampton, who so devotedly treated in the schools of Port Louis all the children affected with that disease.

It must be borne in mind that this heading comprises all cases of anæmia detected among the children during my inspection, irrespective of the cause or causes which might have brought that condition, that is to say, enlargement of the spleen, general debility, defective development, worm infections and poverty.

The figure for schistosomiasis is about the same.

There is a marked decrease in the figure for other worm infections, due very likely to the treatment applied for hookworm by Dr. Hampton.

343 pupils were found with enlarged spleen.

On the whole and notwithstanding the favourable climatic condition for the spread of malaria which prevailed during a greater part of the time between February and June, a marked improvement, calculated on sufficient data, has been registered as regards the decrease in both the percentage and the average spleen noticed during this first half-year.

Anti-Malaria Work in Plaines Wilhems.

In Curepipe, seventeen cantonniers under a moustiquier have carried out the usual cleaning of the existing channels and rivers.

Several ponds and marshy places have been filled up. *Anopheles costalis* have been found from time to time. *A. funestus* and *A. maculipalpis* have not been found.

A. mauritianus is frequently met with in the forest grounds and in springs and marshes which are so common in Curepipe.

In the Quatre Bornes Section, both *A. costalis* and *A. maculipalpis* have been found in Candos Mountain drains and in the neighbourhood of Mount Corps-de-Garde, and in the intervening area between these two points—twelve cantonniers and a moustiquier carry out this work.

In Beau Bassin and Rose Hill there are no works directly carried out by the department. *A. costalis* have been found in roadside gutters, in various water nuisances arising from the defective drainage channels from irrigation canals and broken water pipes and defective public fountains. These latter defects are common to all sections as are also defective "prises" and "regards." The irrigation canal work is the duty of Syndics and private owners and recourse has to be made to the Law Courts to effect repairs.

Plague.

The outbreak of human plague in Plaines Wilhems synchronized with the discovery of rat plague. The latter proved to be very extensive. The commencement was in October and human plague continued till the end of February. Two estates were attacked, viz.: Highlands and Ebène—fortunately, three and two cases respectively were all that occurred in them. In Ebène, many rats were found in storehouses and quantities of fleas were found in gunny sacks and cereals.

The prophylactic measures besides disinfection, the liberal use of paraffin and soap emulsion on floors, segregation of patients and contacts and observation of neighbours, included vaccination and control of deaths.

Over a hundred deaths were controlled by spleen, liver and lung punctures. In five cases the disease had not been suspected or certified as plague during life.

The type of native hut and cow shed built of loose stone, walls and superstructure of thatch is a real menace in urban areas. Many plague rats were found in these buildings. There is no doubt that plague is really endemic in these places and recrudescences of human plague must occur under the conditions referred to.

Many orders have been served for shops and houses (concreting of floors and repairs to make rat-proof) throughout the district.

Eight thatch houses were burnt in Planes Wilhems in connection with plague in 1923.

103 cases of infectious diseases occurred in Plaines Wilhems in 1923, i.e., enteric fever, diphtheria, septicæmia, puerperal fever, erysipelas, cerebro-spinal fever, measles, and whooping-cough with enteritis.

Annual Report of the Bacteriological Laboratory for the Year 1923.

The number of specimens and articles received at the Bacteriological Laboratory during the year 1923 totalled 3,014, showing an increase of 1,164 on the number for the preceding year. They may be classified as before, for facility of discussion, under the following heads:

Clinical.

The samples coming under this head, exclusive of vaccines, amounted to 2,356. Of these 203 were submitted to bacteriological examination involving cultures and animal tests when required. The materials dealt with comprised blood, throat swabs and false membranes, sputum, fæces, pus and pathological exudations, urine, cerebrospinal fluid, neoplastic growths, &c.

(*a*) *Blood.*—1,077 samples were examined.

Malaria.—217 samples came in for this disease. Parasites were found in twenty-one cases as follows: subtertian in eleven, tertian in nine, quartan in one.

Filariasis.—Eighteen samples were examined for filaria embryos; *Microfilaria bancrofti* was found in four.

Plague.—Plague bacilli were discovered in four out of eleven smears of gland or spleen juice from suspected cases. None were found in a sample of blood from a similar case.

Typhoid and the Paratyphoids.—These diseases accounted for 350 specimens. 288 of these were submitted to Widal's test for agglutinins with positive results (one in thirty and higher dilutions) in ninety-two cases. Blood culture on bile-salt broth was done in seventy-two other cases with success in fourteen.

Syphilis.—261 samples were tested for the Bordet-Wassermann complement fixation reaction. Positive findings were obtained in ninety-two and doubtful ones sixty-six instances. The antigen used is prepared from human heart muscle.

Blood counts.—Ninety-three differential leucocyte counts were made and one red corpuscle count.

Chlorides and Urea.—One sample was sent in for a quantitative estimation of chlorides and eighty-nine for a quantitative estimation of urea.

Malta Fever.—Agglutinins for *M. melitensis* were looked for in the blood of a patient suspected to be affected with this complaint, but the reaction proved negative.

Bacteriological examinations.—In the seventy-five cases in which a blood culture was made fourteen yielded *Bacillus typhosus*, seven yielded streptococci, four yielded staphylococci, two yielded *B. coli communior.*

(*b*) *Throat and nose swabs* were received on seventy-two occasions. The Klebs-Löffler diphtheria bacillus was found on thirty-six and Vincent's fusiform organism on thirteen, with or without other bacterial associations.

(*c*) *Sputum.*—Samples received 168. Examined principally for Koch's tubercle bacilli and pneumococci. The former were present in thirty-seven and pneumococci in predominating numbers in four.

(*d*) *Pus.*—Number of samples seventy-eight. The materials were derived from abscesses, boils or were specimens of urethral or vaginal discharges. Gonococci were found in three, while twelve samples of closed abscesses proved sterile. Of the twenty-eight specimens that were successfully cultured, twenty-one gave staphylococci and seven streptococci.

(*e*) *Cerebro-spinal Fluid.*—Specimens examined twenty-nine. Four came in for a Wassermann test of which two gave positive results; the colloidal gold reaction was applied to seven others, positive in six instances; a leucocyte count was made with three samples while three others were tested quantitatively for albumin and one for glucose. Eleven more were examined for their bacterial contents: four showed pneumococci and one meningococci. Six were free from micro-organisms.

(*f*) *Pleural Fluid.*—Four samples were received, two for cytological study and a leucocyte count and two for bacteriological investigation. From one of these a streptococcus was isolated.

(*g*) *Cystic Fluid.*—The liquid contents of a cystic tumour of the foot were examined and cultured without results.

(*h*) *Bile.*—A sample was tested for micro-organisms of the typhoid group, with negative results.

(*i*) *Hydrocele Fluid.*—Search was made unsuccessfully for filaria embryos in the tappings from a case suspected to be of filarious origin.

(*j*) *Synovial Fluid.*—No micro-organisms could be demonstrated either by microscopical examination or culture in a case of synovial effusion.

(*k*) *Hairs.*—A number of specimens were received and examined for fungi.

(*l*) *Fæces.*—Samples 488. *Amœba histolytica* present in forty. Other entozoa were also found in the course of these examinations, i.e., trichuris, ankylostome, ascaris, trichomonas, blastocystis, lamblia, anguillula stercoralis, oxyuris and coccidia.

The coccidia were found in diarrhœic stools in association with no other known pathogenic organism. No alternate cause could be found for the recurrent attacks of diarrhœa from which the patient was suffering and there seemed to be good grounds for incriminating the coccidia. In fresh stools only ovoid oöcysts were seen with undifferentiated granular contents, but after standing for a few days the oöcysts were found to have developed two sporocysts containing four sporozoits each. In short, the organism closely resembled the sexual form of *Isopora hominis*. Treatment proved of no effect. It is the first case of human intestinal coccidiosis registered at this laboratory. The patient had been abroad some time previously so that the infection may have been acquired out of the colony.

Six samples of stools were cultured: from two *B. coli communis* (Escherich) and from a third *B. coli communior* were isolated.

Colonial Medical Reports.—No. 171.—Mauritius (*contd.*)

(*m*) *Urine.*—413 analyses were made. Most of these consisted of the usual routine clinical procedures, chemical and microscopical, but in sixty-seven cases the centrifuged sediments were cultured with the result that staphylococci were isolated, also *B. coli communis*, *B. lactis aerogenes*, *B. coli communior*, *B. paracoli*, streptococci, one diphtheroid bacillus, one Gram-negative unidentified organism, and twenty-four sterile.

Microscopical examination of the sediments also showed eggs of *Schistosoma hæmatobium*, hyaline casts, granular casts, waxy casts, filaria embryos, gonococci and trichomonas.

(*n*) *Neoplasms.*—Sixteen specimens were cut and sections examined. They consisted of fibroma, fibro-sarcoma, sarcoma, myxoma, carcinoma, epithelioma (squamous), papilloma, bilharzia polypus, salivary gland (normal). In addition, portions of muscle tissue were also examined for trichinæ with negative results and sections were made of the heart muscle, kidney and lung in a case where fatal poisoning with carbon tetrachloride was suspected.

(*o*) *Catgut.*—Complaints having arisen regarding the quality of the catgut supplied to the hospitals, an investigation was undertaken by this laboratory in the course of which eight different specimens were bacteriologically examined, all but two of which showed a contamination with a spore-bearing bacillus or a small Gram-negative organism, or with both.

VACCINE.

(*a*) *Prophylactic Vaccines.* — Antityphoid and T.A.B. vaccines were prepared as before for prophylactic purposes and issued free of charge. 866 applications were received from the former, but the demand for the compound vaccine was much smaller, being limited to 180 persons.

(*b*) *Therapeutic Vaccines.*—The following autovaccines were prepared, from blood: with *B. coli communior*, *B. typhosus* and *streptococci;* from urine: *B. coli communis*, *B. coli communior*, *B. lactis aerogenes*, *B. paracoli* and *staphylococci;* from pus: staphylococci, streptococci; from fæces: *B. coli communis* and *B. coli communior.*

Spleen smears from seventeen rats were examined for the sanitary authorities with positive findings as to plague in two instances.

RESEARCH.

Work done under this head comprised:

(*a*) A continuation of the previous searches for the intermediate host of *Schistosoma hæmatobium* in Mauritius.

(*b*) The application of micro-spectroscopy to the determination of blood stains for medico-legal purposes.

(*c*) A study of human intestinal coccidiosis.

Colonial Medical Reports.—No. 172.—Madras.

ANNUAL REPORT OF THE HEALTH OFFICER OF MADRAS FOR THE YEAR 1923.

VITAL STATISTICS.

A marked feature in the climatic conditions of the city during 1923 was the abnormal drought caused by the scanty rainfall, the total rainfall for the year being 37·33 in.

The number of births registered during the year 1913, exclusive of still-births, was 22,975.

The number of deaths registered during the year, exclusive of still-births was 19,933. The number of deaths registered among Europeans was forty-three, Anglo-Indians 288, Indian Christians 886, Hindus 16,324, Mohammedans 2,388 and others four. These figures are somewhat interesting in that they show that the healthiness or otherwise of any community is largely influenced by the social and economic conditions under which they live.

CAUSES OF MORTALITY—INFECTIOUS DISEASES.

Malaria causes 3·9 per cent. of the total deaths.

There were fifty-one deaths from enteric fever during the year.

Fifty-two deaths from kala-azar were registered from this cause.

Fifty cases of cholera were reported in a sporadic form during the year, of which twenty-one proved fatal.

The incidence of this disease was greater in the months of August and December than in any other month of the year. The following special steps were taken to prevent any possibilities of spread of infection from the disease: (1) The private medical practitioners in the city were informed through the press that they might send patients suffering from cholera or small-pox at an early stage to the infectious diseases hospitals at Rayapuram or Krishnampet and attend upon and treat the cases themselves at the said hospitals. (2) Two sub-assistant surgeons in each range were given training in Roger's method of treating cholera cases so that they might treat the cases at the residences of the patients, whenever necessary and whenever there might be a regular outbreak. (3) Pamphlets on "Cholera and Flies" in English and Vernacular were printed and distributed broadcast to the public. (4) Posters about cholera were put up at public places.

Small-pox was prevalent in the city throughout the year in a sporadic form, the number of attacks during the year was 481, of which 151 proved fatal.

Suitable preventive measures were taken and the disease was greatly kept under control.

There were twenty-five deaths from measles during the year.

The total number of deaths registered under influenza was nineteen for the year.

There was one attack and one death from an imported case of bubonic plague against one attack and one death in 1922.

3,778 deaths were recorded during the year from diarrhœa and dysentery.

Diarrhœal diseases are almost entirely water-borne and a fall in their incidence can only follow in proportion to the improvements that can be effected to purify our water supply and the control we can exercise upon the sale of articles of food and drink.

3,342 deaths were registered from general respiratory diseases, excluding tubercle of the lung.

1,268 deaths were registered under tuberculosis, including tubercle of the lung, an increase of 180 deaths to the previous year. Diseases due to infection by tubercle bacilli appear to be on the increase. The figures available in statistical tables may not represent the whole truth. For, on the one hand, in the wide group of tubercular infections that affecting the lungs is alone made notifiable since 1920, while, on the other hand, the notifications received do not reveal the exact number actually suffering from tuberculosis of the lungs. Although it may be argued that the presence of the Tuberculosis Hospital and Institute in the city attracts a good number of cases from the mofussil and, therefore, the rise so far as this city is concerned is only apparent, yet the general consensus of medical opinion seems to agree that the disease is actually on the increase. The remedy is to segregate in the house as best as possible all open cases of lung tuberculosis, i.e., patients who throw out a large number of active bacilli in their sputum and to relieve overcrowding and poverty. What is needed is a general scheme for prevention of tuberculosis for the whole presidency if the city should be saved from its ravages.

2,040 deaths were registered under diseases of the nervous system. Of these, 1,440 deaths were recorded among infants under one year of age.

During the year there were sixty-two attacks and two deaths from relapsing fever which was prevalent for about five months from December, 1922, amongst the chucklers and scavengers. The disease was brought under control, each case being immediately removed to the Infectious Diseases Hospitals for treatment after examination of the blood for the presence of spirochætæ and the patient was promptly treated with neosalvarsan given intravenously. The bodies and clothing of contacts were cleansed and freed from verminous conditions so largely prevalent amongst that class of people.

Vaccination.

Vaccine lymph for the operations was obtained from the King Institute of Preventive Medicine, Guindy. The total number of vaccines performed during the year 1923 was 36,629. The number of revaccination cases has perceptibly decreased, consequent on the absence of an epidemic of small-pox, while primary vaccinations have shown a rise and this, in fact, is the real index of vaccination work.

Of the total number of primary vaccinations (17,900), 15,899 were among children under one year of age.

The total number of births verified during the year was 17,217. Of them, 3,453 died during the year.

Sanitation.

Water Supply.—As a result of discussions in the Council in respect of the quality of water supplied to the city, an analyst was appointed to examine and report on it. A laboratory was constructed at Kilpauk within the water-works compound to facilitate the examination of samples of water at various stages of its purification. The report of the analyst in this behalf is appended. The report indicates that the water supplied to the city is far from pure and water after undergoing filtration does not attain to a sufficient standard of purity either chemically or bacteriologically as to make it all wholesome. Unsatisfactory as this may be, the matter is receiving due consideration at the hands of the corporation. Since my annual health report for 1922 was written, the Government Water Filtration Committee submitted their report to the corporation, who, after a discussion at one of their meetings, referred the question back to the government for a further report by the said committee and for obtaining the expert advice of Colonel Clemesha, I.M.S. (retired). Pending the receipt of these reports, the corporation have not been in a position to launch upon further schemes for effectively purifying the city water supply. In the meantime the best and safest course for the people to do is to collect the water from the tap after passing it through a thick piece of cloth and boil and cool all that part of it at least which is used for drinking.

Drains.— It is the duty of the Health Department to advise the Works Department to construct and maintain drains for the efficient carriage of sewerage and sullage in certain localities where they are likely to improve the sanitary environments. Drains were accordingly constructed.

Streets.—Certain important streets and thoroughfares in the city are now being tarred and a great deal of nuisance from dust is thus abated. There yet are several important and busy localities where nuisance from dust is a real danger from the public health point of view. It seems necessary to extend the refining of roads so as to make them dustless even at some large initial cost. Dirt and dust are true breeders of disease and they should be allayed by all practicable means.

Control over Waters.—Municipal control over tanks and wells cannot at present be said to be satisfactory. It is a well-known fact that there are a number of public tanks which are kept in a bad state so as to be a source of nuisance and

danger to public health. During the year action was taken in respect of sixty-one cases to get the tank or well cleaned up. But this is very inadequate as there are many large tanks in the city which act as breeding places of mosquitoes. It has been proved that many wells in George Town breed the type of mosquito that carry malaria to man. Control over waters and waterways in these days is called for mostly for anti-malarial purposes. That Madras is an endemic area for malaria and that there are plenty of breeding grounds for mosquitoes have been amply proved by an investigation consequent on the outbreak of malaria in an epidemic form in 1912 and 1913. The corporation started with the assistance of a government campaign against malaria which continued to work on actively till April, 1921. Since the latter date it was practically given up on financial grounds and except for a small set of nine coolies and a Maistri for cleaning the anti-malarial drains the whole establishment was abolished. As at present, before action could be taken under Section 264 regarding these places we have to satisfy ourselves that mosquitoes do breed and that they are carriers of disease. This would require a special staff to investigate from time to time. Anti-malaria work such as oiling and cleaning, removing weeds, &c., requires a special set of men trained for the work and the corporation must maintain a set of these coolies for this purpose. Private tanks, wells and pools are so numerous in the city and so insanitarily kept that some method of controlling them and keeping them sanitary is immediately called for. It is suggested that these places may be licensed by the department, so that we could have a control over the owners, to make it obligatory on their part to maintain them in good condition and the corporation could get the necessary work done from time to time by sending out the special staff and recovering a fee for the work done. The difficulty is that even if we take action under the Madras Municipal Act owners of tanks and wells, &c., cannot find and procure the trained labour for this kind of work. The Cooum and the Buckingham Canal continued to be in the same condition as recorded in my last report. It is the duty of the Government Public Works Department to remove silt from these from time to time and keep them clean. They require greater attention at their hands than at present. The corporation cannot at the same time relieve themselves of their responsibility in the matter, as a fair and considerable proportion of sewage is let into these water channels at various points of their course through the city. This can be stopped only when the city is completely sewered.

Disinfectants.—Hycol and chloride powder were the two disinfectants chiefly used during the year.

The medical officer of the Krishnampet Isolation Hospital and others delivered lantern lectures on small-pox and other subjects in the various parts of the city during the course of the year.

In pursuance of the resolution of the council at its general meeting held on February 20, 1923, the work of medical inspection of the elementary schools under the corporation of Madras was entrusted to the medical officers in charge of the twelve corporation dispensaries.

Hospitals and Dispensaries.—Two infectious diseases hospitals, one at the Old Jail Road and the other at Krishnampet, continued to serve a useful purpose and were in charge of sub-assistant surgeons. The latter has accommodation for ninety beds. The motor ambulance was in use during the greater part of the year. These hospitals are increasing in popularity. The new infectious diseases hospital at Tondiarpet is under construction.

The dispensaries were in charge of sub-assistant surgeons. Owing to the usefulness of these institutions four more dispensaries were opened during the year at Nungambakam, Mannady, Mafuskhan Garden and Mint Street. The proposal that a municipal dispensary might be made a unit of registration and vaccination district was sanctioned by the council and accordingly provision was made in the current budget for three more dispensaries.

These institutions were largely attended by the middle and poor classes of people residing in and about the place where they are located.

Report on the Work in the Corporation Water Analysis Laboratory for 1923.

Laboratory work as organized at present is chiefly of a routine nature and consists of: (1) Preparing media for bacteriological work (nutrient agar, nutrient broth, MacConkey's agar, MacConkey's broth, sugar media for water analysis, strong peptone water for cholera work, weak peptone water, glucose medium for Voges and Praskaur's reaction and Aronson's medium for cholera work). In addition, sterilization of pipettes, bacteriological sample bottles, Petri dishes, &c. (II) Collection of bacteriological and chemical samples, three per day and even more occasionally. (III) Bacteriological analysis (total colonies count in 1 c.c. of sample, inoculation of tubes of MacConkey's bile salt broth with various quantities of water, vibrio test in 100 c.c. of the test tap sample and microscopic examination of sediments). (IV) Chemical examination, qualitative consisting of colour and transparency, smell, nitrite, nitrate and sulphate, &c., and quantitative examination, consisting of ammoniacal nitrogen, albuminoid nitrogen and absorbed oxygen (Tidy's). (V) Any other work which the health officer or the special engineer through the health officer may suggest.

Analysis of the raw water shows that its organic content as represented by the "ammonias" varies considerably. The figures for "ammoniacal nitrogen" and "albuminoid nitrogen" vary between a trace and 0·004 in the former case and 0·030 to 0·048 in the latter case. The results of bacteriological examination show that lactose fermenters are present in as small a quantity as 1 c.c. and upwards in 59 per cent.; in 5 c.c. and upwards in 30 per cent.; and in 10 c.c. and upwards in 11 per cent. of the analyses, the average total number of colonies per c.c. being about 1,200.

The filter beds yield, at times, filtrates of good quality or of fair quality; and at other times of a quality which shows no improvement over raw

water. The results of filtration as judged by the chemical examination of samples of water are not satisfactory. A smell of sulphuretted hydrogen was noticed in the regulator chambers of the filter beds, on almost all occasions, the intensity of the smell varying during different seasons of the year. This odour was present throughout the year and was more conspicuous in summer than in other seasons of the year. In the case of "free ammonia" variations between a trace and 0·019 are to be found. The figures for "albuminoid nitrogen" and "absorbed oxygen" are also excessive.

Vibrio Test.—On August 30, 1923, the analyst was asked to make bacteriological tests with special reference to the presence of cholera or cholera-like sprillum in water sent to the town supply, as there were a few cases of sporadic cholera in the town. Samples from the test tap on the main which leads to the city supply were specially tested for vibrios and the examination showed negative results. Since then testing for vibrio in the town supply has become a part of the routine work of the laboratory and on no occasion during the year under review the presence of cholera or cholera-like vibrios was detected.

Microscopic Examination.—Systematic examination of suspended matter in raw water and of the "filtering skin" or "schmutzdecke" every time a filter bed was scraped was made under the microscope.

Growths of Organisms in the Covered-in Masonry Conduit.— About January 21, 1924, the cleaning of the conduit was started. Till about the 15th manhole there was no thick growth of any kind excepting some water insects which were found adhering to the sides of the wall above the surface of water. Abundant growths of a brown colour were seen after the 15th manhole, sometimes covering a length of ten to fifteen feet, and often in discontinuous patches, whose thickness varied from ¼ in. to 1 in. The same growth was found to extend to the Kilpauk end of the conduit. It grew under water, on the sides of the conduit. Samples of the stuff were collected and were identified to be a polyzoon by Dr. Gravely of Madras Museum, who sent it to Dr. Anandale, the leading specialist in the group, for identification of the species. It was found to be *Plumatella* (Afrindella) *tanganyikæ*, Rousselet, a not uncommon species in India. Imbedded in this there was also plenty of epistylis. The sample contained, in addition to plenty of statoblasts of plumatella, anguillula, water flies, &c.

It may not be out of place here to give an account of the family of polyzoa.

"The family of polyzoa is one of the most interesting branches of the animal kingdom. The massy growth consists of branched tubules growing from a common stem in the form of a living tree. Each branch is inhabited by a complete animalcule provided with mouth, stomach, rudimentary alimentary canal and genital organs. Its prey consists of micro-organisms, bacteria, &c., which are swept into the mouth by the movements of an array of tentacles which are protruded at intervals in the water. The whole form a colony of individuals housed in the branches of a common zoological tree, which is itself alive. Polyzoa are most fascinating objects to watch under the microscope."

Miscellaneous Work Done During the Year.—(*a*) In September the special engineer desired the analyst to make qualitative tests for the smell evolved in the regulator chambers of the filter beds, as, in his opinion, the odour varied from "earthy" to SH_2 smell. Accordingly, several qualitative tests were carried out which conclusively proved that the smell was of sulphuretted hydrogen. One of the tests was the lead acetate test. Filter papers soaked in an alkaline solution of Pb $(C_2H_3O_2)_2$ were suspended about a foot over the water in the filter chambers. They were collected next morning and the results were recorded.

(*b*) Experiments on the correct dosage of chlorine and the minimum period of contact for producing sterility on the effluent from the "double filter."

The analyst carried out these experiments. The first portion was done according to Sims-Woodhead Field test modified by Morrison and the latter portion of the experiments was carried out as follows: The dose of chlorine for the effluent from the "double filter" was determined by "Field test" first. Next, six different beakers were taken, each containing 500 c.c. of the effluent and to each was added requisite amount of bleaching powder solution, corresponding to the dose of chlorine, previously determined by "Field test." After the addition of the bleaching powder solution, all the beakers were stirred by glass rods, so as to have a homogeneous mixture. The first beaker was allowed ten minutes contact, next twenty and the last sixty minutes contact. After the end of each period, a set of MacConkey broth tubes were inoculated with water from the respective beakers and incubated for forty-eight hours at 42°C. The results at the end of forty-eight hours were recorded.

The dose of chlorine for raw water varied from 0·8 to 1·0 part per million, while that of the effluent from the "double filter" from 0·7 to 0·8 part per million. The minimum period of contact for producing sterility on 500 c.c. of the effluent from the "double filter" was 10 minutes.

Report on the Medical Inspection of the Corporation Elementary Schools.

The most striking fact that emerges from the examination is the prevalence of infectious or contagious diseases including skin affections and of tuberculosis, viz.: 2·01 per cent. and 0·32 per cent. respectively of the boys examined. What need to be done in regard to these children are these: absolute exclusion of those suffering from such diseases as leprosy and infectious or contagious disease, especially of skin and of open tuberculosis, i.e., cases in which sputum infected with tubercle bacilli is expectorated; advice to parents for treatment of such cases, either in hospitals or elsewhere, and examination of all children before admission to schools by the medical inspectors.

Colonial Medical Reports.—No. 173.—Ceylon.

REPORT OF THE PRINCIPAL CIVIL MEDICAL OFFICER AND INSPECTOR-GENERAL OF HOSPITALS FOR THE YEAR 1923.

Public Health.

181,441 births were registered and 141,894 deaths during the year.

The more notable causes of death were the following disease: Infantile convulsions, diarrhœa, pneumonia, rickets, intestinal parasites, anæmia, dysentery, phthisis, dropsy, malaria, ankylostomiasis and its *sequelæ*, puerperal septicæmia, enteric fever, tetanus, rabies and deaths attributed to pyrexia of unknown origin.

A large number of the deaths registered under pyrexia of unknown origin were undoubtedly due to malaria or diseases concurrent with it, as this disease was very prevalent in the greater part of the island.

Infantile Mortality.—16,166 deaths from infantile convulsions were registered during the year, and this number represents 11·39 per cent. of the total number of deaths registered, which indicates the need for child welfare centres and créches, antenatal clinics, and trained midwives. Some endeavour to aid mothers in the care of their infants is being made in the larger towns by social service circles.

Malaria was very prevalent and showed a marked increase as regards hospital admissions, and cases treated at dispensaries and hospital out-patient departments over the large numbers of the previous year. 2,118 deaths from malaria were registered in 1923; but 23,328 deaths in 1923 were registered under pyrexia of unknown origin. Many of these were probably due to malaria.

Quinine to the value of Rs. 276,120·96 was issued free for preventive and curative purposes. It was distributed by itinerating apothecaries and vaccinators on fever duty and by headmen through the Government Agents during the fever seasons.

Education and Propaganda.—Public lantern lectures in English and the vernaculars have been given at Anuradhapura, Badulla, Trincomalee and Gampaha, and lantern lectures and demonstrations at schools at Badulla and Trincomalee. An extensive series (about eighty) lantern slides of local application, and several posters, illustrating the more important facts and principles underlying modern methods of prevention and control, have been prepared during the past two years. These slides and posters should prove of considerable educational value, and should be of great service in the future, when malaria propaganda work is definitely organized. Several thousand pamphlets and handbills on malaria have been distributed to towns and villages in various parts of the Island. A malaria exhibit was sent to the Agri-Horticultural Show at Gampaha in July, 1923. This exhibit included a complete series of the anopheles mosquitoes found in Ceylon with enlarged paintings of the commoner and more dangerous malaria carrying species, living malaria and non-malaria-carrying mosquitoes and their larvæ, larvivorous fish (imported and indigenous), and various other specimens of general interest; also photographs and paintings of anopheles breeding places and malaria parasites, maps, posters, diagrams, &c.

A course of lectures and demonstrations on malaria and its control was given during April and May to the Training Class for Sanitary Inspectors held by the Sanitary Branch of the Medical Department.

A useful and instructive pamphlet on malaria was prepared by Dr. L. Nicholls for the use of teachers, and was published by the Department of Education; it has been widely distributed to schools and also to the general public.

Malaria Research and Control Works.—Research work in connection with malaria was continued on the lines indicated in the report for the year 1922. Detailed malaria surveys of the four centres mentioned above and of Trincomalee were completed, and further inquiries instituted into the bionomics and seasonal prevalence of anopheles and other factors influencing the incidence and spread of the disease at these towns. Other investigations included continuance of the work on paddy cultivation and malaria as detailed in the previous report, and an attempt to determine the reasons for the relatively low incidence of malaria in the south-west portion of the island. The results obtained from observations on the breeding of anopheles mosquitoes in paddy fields made throughout a completed year appear to be of sufficient interest and importance to justify an extension of the work. It has, however, been found impracticable to continue examinations every month at all the towns originally selected, and accordingly the work has been restricted to the five centres at which assistants are stationed.

Additional and more precise information relative to the various investigations has been obtained, but since in many aspects the separate lines of work are interconnected, and complete results are not in all cases available, it is considered advisable to defer further discussion to the final report referred to above. Much of the laboratory work connected with these investigations is performed in Colombo; it involves a large amount of routine examination work, particularly during the period of the north-east monsoon, and throws a heavy strain upon the

staff. The inquiries in progress relative to the bionomics, distribution and prevalence of anopheles mosquitoes are largely quantitative in nature, and are for the most part based upon the larval stage of these insects. During the past year such routine work alone has involved the microscopical examination of an average of 4,400 anopheles larvæ per month and a total of 1,448 blood films.

Further collections of larvivorous fish have been made and are awaiting identification. *Haplochilus lineatus*, the species occurring so abundantly in the swampy areas of the Western and Southern Provinces, has now been found in large numbers in swamps and flooded paddy fields on the east coast in the Batticaloa, Trincomalee and Mullaittivu Districts. With the exception of the last-named places the species has been rarely found in the dry zone of Ceylon. Attempts to establish it in the nurseries, for subsequent distribution to wells and non-permanent pools in districts where malaria is intense and larvivorous fish relatively scanty, have not proved very successful. Much more promising results have been obtained with the West Indian species *Gambusia affinis*—" Millions "—which is not only more voracious and prolific, but less susceptible to changes of environment. With care and attention " Millions" should eventually become established throughout the greater part of the island, when their periodical distribution to wells and non-permanent pools should afford a valuable measure of control. Additional nurseries for both species were opened at Jaffna in September; *Gambusia* increased sufficiently in numbers to allow of their initial distribution in November to wells in which *Anopheles* was breeding Distribution of " Millions " to wells and pools was also carried out at Talaimannar and Trincomalee during the last few months of the year.

Malaria control measures have been in operation during the past year at Anuradhapura, Trincomalee, Mahara Jail, Kurunegala and Badulla. The campaigns at Anuradhapura and Trincomalee are intended to serve as demonstrations and it is hoped will indicate the nature and value of anti-malaria works in the low country; they are under the control and direction of this office, but are conducted in close co-operation with the local authorities, who also assist financially. At Mahara Jail, where a serious epidemic occurred in 1921, the works recommended have been carried out under supervision of jail superintendent and the resident medical officer; the results for the past year have been satisfactory, and a continued steady drop in the curve for hospital admissions for malaria has taken place since May. At Kurunegalla and Badulla anti-mosquito measures of a minor nature have been performed by the local authorities, but it is doubtful whether such measures alone can produce any marked effect upon the incidence of malaria. At both of these towns the work is greatly handicapped by lack of funds, and—of equal importance—a trained staff to direct and control initial measures.

Cholera.—There has been no outbreak of cholera in the island for three years. The last case occurred in 1920

Small-pox.—There was an outbreak of small-pox in Kandy at the end of the previous year, and the disease was carried to several centres of infection during the first quarter of the year by absconding contacts. 200 cases with thirty-one deaths were reported from the Central Province, twenty-six cases with two deaths from the Western Province, five cases with one death from the Province of Sabaragamuwa, and one case from the North-Western Province.

Five cases were landed in Colombo from steamers, and three cases occurred in Colombo town, with one death.

There were 240 cases with thirty-five deaths.

Vaccination.—The total number of primary vaccinations performed during the year was 138,092; of these, 124,462 were successful and 1,859 were failures. In 11,771 cases the results were not determined.

Government Vaccine Establishment.—The officer in charge reports 480 calves were received on hire from the contractor; 474 calves were used for vaccination during the year; and of these, 466 were returned.

Seed lymph for the vaccination of calves was obtained from the Lister Institute of Preventive Medicine, London, and from the King Institute, Madras; and was also prepared locally. 160,593 tubes of calf lymph were issued from this establishment during 1923.

Enteric Fever.—The total number of cases treated in Government hospitals during the year was 921, with a death-rate of 29·31 per cent. Patients are usually taken to the hospitals for admission in late stages of the disease and the mortality rate is therefore high. These figures do not indicate the extent to which enteric fever prevails in towns and rural districts generally. Probably many cases occur which are neither recognized nor reported. The Registrar-General's returns show that 597 deaths from enteric fever and 23,328 deaths from " general fever " (pyrexia of unknown origin) were registered during the year, and undoubtedly some of the latter should have been included in the former.

Diphtheria.—This disease rarely occurs in the island. Only fifteen cases with six deaths were recorded during the year; and of these, eight cases were treated in the Infectious Diseases Hospital, Colombo.

Influenza.—A mild form of influenza prevailed in all the provinces at different periods of the year. 4,443 cases were treated in Government hospitals with 162 deaths, a mortality rate of only 3·64 per cent. 23,372 cases were treated at dispensaries during the year.

Dysentery.—There were outbreaks of dysentery in the Western and Southern Provinces, and this disease was unusually prevalent during the year, due probably to the abnormal rains. The number of cases treated in Government hospitals was 5,884, with 993 deaths. 25,516 cases were treated at dispensaries during the year. The most common source of infection is the drinking water, which is only obtainable, in many villages, from shallow, un-

protected wells liable to pollution; but it is possible that contaminated food, and especially green vegetables, plays an important part in the dissemination of this disease. 3,326 deaths from dysentery were registered by the Registrar-General's Department during 1923.

Cancer and Sarcoma.—The number of patients admitted to the various hospitals during the year with malignant growths was 443, with fifty-nine deaths.

Ankylostomiasis.—114,157 cases were treated at dispensaries during the year. These figures refer to cases of ankylostomiasis as the primary disease; but owing to the almost universal infection of all hospital and dispensary patients, mass treatment for this disease was carried out during the year at dispensaries and the out-patient departments of hospitals and a large number of persons received necessary treatment.

Tubercular Disease of the Lungs (Pulmonary Phthisis).—The number of hospital cases treated during the year was 4,099 with 990 deaths.

Three special institutions—The Anti-Tuberculosis Institute, Colombo, the Kandana Sanatorium for early cases, and the Ragama Tuberculosis Hospital for advanced and chronic cases—are maintained to deal with this disease. A large number are yearly admitted to the tuberculosis wards of the General Hospital, Colombo, for want of sufficient accommodation at Ragama.

Leprosy.—Two asylums are maintained in the island for the segregation of lepers under the Lepers Ordinance—at Hendala in the Western Province and Mantivu Island in the Eastern Province.

The lepers are nursed by religious sisters with the help of male and female attendants at both asylums.

There were 116 lepers at Mantivu Island on December 31, 1922. Fifty-eight were admitted during the year under review (and of these, only twelve were new cases), thirteen died and forty-seven were discharged or absconded. 114 remained on December 31, 1923.

The medical superintendent reports seventy-nine lepers were treated during the year with E.C.C.O., the recently-discovered treatment for leprosy, and that the results have not been as discouraging as in past. In tubercular cases, if taken in hand early, and if the patients are of a robust constitution, there is a marked diminution in the size of the nodules and rapid softening of the skin. The best results are in the anæsthetic cases—sensation and colour of affected areas rapidly return. In all cases there is improvement in general health.

A female patient was discharged on parole, as she was apparently cured, and is being kept under observation. Four cases have shown such marked improvement under the treatment that it is hoped to be possible to discharge them as cured at an early date. It is expected that these results will encourage patients in the first stage of leprosy to seek treatment.

About four-fifths of the lepers in the asylum are in the last stage of the disease and of the advanced crippled nerve type, and these can only hope for some improvement in their general health from the new treatment.

Parangi (Frambœsia, or Yaws).—The number of hospital admissions was 9,748, with thirty-two deaths. The decrease in the number of hospital cases during the year was due to intensive campaigns by three itinerating medical officers and the treatment by modern methods weekly of a large number of out-patients brought by headmen to, and voluntary seeking treatment at, dispensaries and the out-patient departments of hospitals.

Plague.—There were 232 cases in 1923 with 211 deaths. Of the 232 cases reported during the year, eighty-four males and thirteen females were admitted to the Infectious Diseases Hospital, Colombo; and of the total treated during the year, 15·68 per cent. recovered.

Port Health Precautions.—During the year 2,363 British and foreign steamers and 285 native sailing vessels called at the Port of Colombo and were inspected.

Intravenous Protein Therapy in Septic Polyarthritis by Dr. E. C. Spaar, Physician, General Hospital, Colombo.—Female, aged fifty, admitted September 20, 1923, with swelling of shoulder, elbow, wrists, knee and ankle joints of three years duration. She stated that the trouble started with swelling of both knee joints unaccompanied by fever. Four days later the shoulder joints were involved and gradually the swelling spread to the other joints. On examination, the mouth was found very septic with marked pyorrhœa and was undoubtedly the source of the infection. The thoracic and abdominal organs appeared healthy. The pyorrhœa was treated by touching the edges of the gums with a weak solution of tincture of iodine and later of hydrogen pyroxide, which was also used as a mouth wash, and one injection of fifty million coli organisms was given intravenously in 10 c.c. of normal saline with due precautions on October 4, 1923, in accordance with the technique of Auld and Gow in England and of Pederson in America based on the researches of Nolf, all of whom have done so much to explain and perfect this new method of therapy. No untoward results followed, with the exception of severe pain in the elbow joints, which was complained of on the following day. Unfortunately, the patient refused to remain in hospital for further treatment, but on her discharge on October 8 there was no swelling in the lower extremities, and although the elbow joints were still swollen she was able to flex them and they seemed more supple. There would seem to be a promising future for this method of treatment in suitable cases.

Investigations on the Control of Hookworm Disease—Larval Activities by Dr. L. Fabian Hirst, Municipal Bacteriologist, Colombo.—The movements and general activities of the mature infective hookworm larvæ are very characteristic and remarkable.

Placed in water in a shallow cell the active larvæ exhibit frequent lashing movements, eventually finding their way to the margins of the cell, where they remain head outwards in a continual state of agitation.

Movement increases with rise of temperature to blood heat. At lower temperatures movements may not be continuous, larvæ sometimes passing into a resting stage, during which there is practically no expenditure of energy.

Larvæ in soil are found in the moisture film covering the soil particles. Their action is exerted between the resistance of the particle and the surface tension of the moisture film. After travelling some distance through soil larvæ became noticeably more transparent, due to loss of their food granules, which, when numerous, render them opaque. The smaller the size of the soil particles the greater the surface tension of their moisture film, the greater the resistance to larval movement and the more rapid the exhaustion of the larval store of energy, which cannot be replenished from without.

Observations made in the laboratory indicate that in a soil such as cabook, permeable to water, but resistent to larval motion, larvæ will remain more or less stationary for long periods if water is regularly added.

Till recently the idea prevailed that hookworm larvæ had great powers of lateral diffusion from an infected focus. This is certainly not the case. The slight lateral migration detected in Colombo soil was easily accounted for by the mechanical action of the currents set up after addition of water to the soil. Observations in the West Indies lead to a similar conclusion. If the moisture content of the zone surrounding the infected fæces be artificially increased on a horizontal plane lateral migration will take place, but such conditions can seldom occur in the field.

Till recently many sanitarians considered that hookworm fæces could safely be buried under a shallow layer of earth without risk of the larvæ developing and ascending to the surface. Recent research shows that burial affords no such security, unless the soil is restrictive of larval movement.

Hookworm larvæ moves upwards or downwards, according to the amount of moisture present in the different levels of the ground; if the ground surface is drying they descend to moister levels; if the upper layers of the soil are moist they ascend till they reach the surface.

The extent of the vertical movements of hookworm larvæ appears to be governed principally by three factors: (*i*) the size of soil particles; (*ii*) the distribution of the ground water; (*iii*) the amount of energy stored up as food granules in the body of the larvæ.

Mature larvæ are usually provided with a sheath which protects them to some extent from adverse influences. After moving even a short distance through compact cabook the sheath is lost.

Loss of sheath is much less marked after passing through a light sandy soil of the Narahenpitiya type. Only twenty per cent. of the larvæ added to cabook can be recovered by Baermann's method, whereas more than eighty per cent. can be isolated from Narahenpitiya soil. Preliminary experiments were made in January and February, 1923, on the vertical powers of ascent of hookworm larvæ. Stools heavily infected with hookworm larvæ and the filariform larvæ of *Strongyloides stercoralis*, after mixing with earth, were buried at the bottom of pits dug in hard cabook near the laboratory to the depths of six, twelve, eighteen and thirty-six inches.

The shallower pits were filled with coarse river sand, Narahenpitiya soil, and loose cabook. Both species of larvæ ascended six inches through all three soils, and hookworm larvæ twelve inches through each soil and through eighteen and thirty inches of sand.

It was proposed to repeat these experiments with definite quantities of larvæ, but in the meantime Florence Payne in America has published a report of such experiments in which numerous larvæ were recovered after an ascent of thirty-six inches through sand. She found in her experiments that the larvæ were unable to penetrate white clay, but ascended ten inches through a red clay.

The behaviour of hookworm larvæ in the surface of soil is of particular interest. Van Durme in 1902 drew attention to the remarkable attitude taken up by the filariform larvæ of *Strongyloides stercoralis* on the surface of particles of soil. Subsequently it was found by other observers that both human and canine larvæ behave in a similar manner. Larvæ attach themselves by one end to a particle of soil, preferably of fibrous nature, and extend themselves into the air. According to the writer's observations the motion of hookworm larvæ in this position is a slow to and fro way movement as if continually reaching for a new support. The *Strongyloides* larvæ exhibit a rapid jerky motion. Florence Payne reports that larvæ do not expend much energy in maintaining this position judging by the rate of disappearance of their food granules.

The larvæ may be observed to move from particle to particle on the surface by a species of looping motion. The aerial position is kept up for periods varying from a few minutes to half an hour or so at a time. Larvæ commonly cling together in aerial clusters which are readily visible to the naked eye on the surface of the soil. The surface of cultures of canine hookworm ova may be covered with waving plumes of larvæ.

The significance of this phenomenon seems clear. Perched in a favourable position on the surface of the soil the larvæ await their opportunity to come in contact with the human skin. So far as is known to the writer, only infected nematode larvæ of the penetrative type behave in this manner. The free-living soil nematodes, though often very active in their movements, remain in the interstices of the soil.

Colonial Medical Reports.—No. 173.—Ceylon (*contd.*)

Immediately contact is made with the skin a new set of forces come into play leading to the penetration of the epidermis, the passage of the larvæ to the lungs, thence to the bronchi, trachea and œsophagus. Full development takes place in the intestines, if the host is adapted to the species of the worm. *Necator americanus*, the Ceylon species of hookworm, has only two hosts, man and the gorilla. The series of forces which brings the larvæ on to the surface of ground moistened by rain, thence to the summit of the soil particles, or as high up as leaves and twigs as the moisture film extends, thence into the skin are analogous to the forces causing a plant to bend towards the light, or which drive a spermatozoa to its destination, the unfertilized ovum.

Pintner named the force thigmotropism which causes the larvæ to penetrate small pores. Brumpt has called the force driving larvæ into tissues histotropism. Khalil has recently described, under the name of thermotropism, the tendency of hookworm larvæ to move towards a heated point. The tendency of these larvæ to extend themselves into the atmosphere may be called ærotropism. It is sometimes difficult to separate hookworm larvæ present in soil from the free-living forms having a somewhat similar appearance.

If a great variety of larvæ are recovered from a mass of soil the task of scrutinizing them all under the microscope in order to make an accurate count of the hookworm larvæ is often excessively laborious.

Progress in hookworm research work has been mainly a question of development in technique. It was Baermann's discovery in 1917 of a convenient and reasonably quantitative method for isolating nematode larvæ from soil which gave the impetus to modern research into the epidemiology of hookworm disease.

The writer has sought to facilitate the task of separating hookworm larvæ from free-living forms by taking advantage of the tropic reactions described above. It was found that hookworm larvæ will penetrate porous membranes, such as filter paper, chamois leather, or buckskin with great ease. Non-porous leathers, parchment, rubber and similar substances are not penetrated. Larvæ penetrate into a membrane made of freshly dissected skin, but seldom pass through it.

The next step is to bring a membrane retaining a suitable fluid at blood temperature in an inverted tube or vessel lightly into contact with the surface of soil containing larvæ. The aerially extended larvæ then pass upwards through the membrane into the fluid where they may be readily recovered free from soil particles and almost free from non-infective larvæ. The results are somewhat affected by the temperature of the atmosphere. It may be necessary to cool the underside of the receptacle containing the soil. A buckskin membrane was commonly used in these experiments.

A curious phenomenon was noted during these investigations (September, 1922, to January, 1923). If a pan of soil showing numerous aerially extended larvæ be placed in the incubator at 37°C all the larvæ disappear from the surface of the soil. They re-appear in a few minutes at room temperature on the laboratory bench.

The technique can be adopted to any quantity of soil. A second test found of value is that of applying the suspected larvæ to the skin of a rat. If the suspected larvæ are able to reach the lung of the rat within three days with production of hæmorrhagic congestion of the organ, the result of the test is considered to be positive. Both canine and human hookworm larvæ give positive results to this test, provided sufficient numbers of larvæ are applied to the skin. Penetrative nematode larvæ of other species would doubtless give similar results. Free-living larvæ give negative results. Tests of this kind cannot entirely replace the crucial experiment of applying the larvæ to the human skin and expelling any hookworms developed, but enable such troublesome experiments to be reduced to a minimum.

The Value of Insulin in Diabetes Mellitus —A Brief Survey of Seven Cases by Dr. Lionel de Silva, Physician, General Hospital, Colombo.— The undue optimism and pessimism with regard to the value of insulin in the treatment of diabetes mellitus in Ceylon is, I think, a sufficient reason for this preliminary note.

A previous experience of a fair number of insulin cases in private practice provided me with the necessary impetus to attempt this treatment in seven cases which were in my wards more or less at the same time.

These remarks are based on the progress of these cases. Diabetes mellitus is not regarded as a definite disease to-day, for it is only a name given to an easily recognized group of symptoms of complex ætiology.

All these patients complained of these common symptoms, viz., polyuria (excess of urine), polydipsia (excessive thirst), polyphagia (excessive appetite), and some progressive wasting of varying degree. This well known group of symptoms, which is aptly regarded by some observers as a definite "syndrome," is due to the excess of sugar in the blood.

Experience of numerous blood-sugar determinations, both in England and in Ceylon, have led to the following conclusions, which will naturally be subject to modification with further knowledge and experience.

That although the physiological variations in the blood sugar, based on the experience of the West, range from ·08 mgm. to ·2 mgm per cent. there is marked difference to be noted in the cases observed in the inhabitants of Ceylon. This difference seems to be based on a racial factor, which bears an important relation to the mode of living and the susceptibility of the nervous system of the various races.

Blood-sugar determinations were made side by side with the urinary-sugar determinations in the private cases referred to. Opinion is unanimous regarding the fact that a single estimation of the percentage of sugar in the blood is very nearly

useless. It is the behaviour of the blood-sugar curve which determines the severity of the failure of carbohydrate metabolism and the dose of insulin given.

The method adopted necessitated a small quantity of blood sufficient to soak a piece of blotting paper half an inch square. The test was conducted in the following order.

First, as soon as the patient comes in after his customary meal taken two hours before the examination, a sample of blood is taken. This determines his normal percentage of sugar. The second sample is taken thirty minutes after the ingestion of 50 grm. of glucose. The third sample sixty minutes after, the fourth ninety minutes after, the fifth 120 minutes after. Five separate samples of urine were taken at the intervals above-mentioned, and the sugar was estimated by Benedict's method.

There was a marked similarity in the behaviour of the blood curve and the urinary-sugar curve in over seventy-five per cent. of the cases investigated.

This simple urinary test has so far been sufficiently accurate to justify its routine use and to supplement the more elaborate blood test, which, however, must be performed once at least in order to eliminate the possibility of the condition known as renal diabetes, &c. This urinary test has been termed by me the "urine tolerance test" for diabetes.

This was the test used in my ward cases in the manner already indicated before commencing insulin treatment. All the seven cases showed a severe type of the disease and gave the typical diabetic urinary-sugar curves similar to those that were given in my previous cases, where combined estimates were done. The first step in my treatment was to withhold the administration of insulin and drugs altogether, the patient being restricted solely to the dietetic treatment. Daily examinations of urine for the next few days showed a diminution on the average of about twenty per cent. of the quantity of sugar originally passed. The value of the carbohydrate diet was considerably under 50 grm. per diem. There was noticed a slight improvement in the symptoms. The urinary-sugar output and the general condition remained unchanged at a constant level for the next few days. This clearly indicated that this treatment has had its maximum effect, and that something more had to be done in the way of treatment.

The second step in the treatment was now begun by the exhibition of drugs, while still continuing unchanged the previous line of dietetic treatment. Drugs were given to stimulate the liver functions and to relieve freely the constipation which is so frequently present in these cases. The result of this combined method brought about a well-marked improvement, but the symptoms of glycosuria persisted to such a degree as to warrant further treatment.

Two of these cases suffered from some surgical complaint which needed operation, and two others had the grave complication of pulmonary tuberculosis which rendered the rapid reduction of the hyperglycæmia imperative.

Then I reached the indication for the third stage of the treatment. It is here that we realize the great boon that has been conferred upon the diabetic by Banting and his co-workers. The urine tolerance test was again done before the insulin was administered, and it was noticed that the tolerance curve was still that of a severe diabetic. Although there was noticed slight improvement in the curve at this stage of the treatment, all the cases justified the use of insulin in 10 unit doses twice a day. The sugar in the urine was estimated twice a day, morning and evening.

The diet and medicines were continued in some cases, and in the others a more liberal diet was given, and the medicines withheld. In the cases where the combinaton of insulin, diet, and drugs were administered at the same time the improvement of the patients was remarkably rapid. The sugar in the urine disappeared entirely in one case by the fifth day and within ten days in the other cases. An emaciated boy of eighteen, for example, gained nearly 20 lb. in weight within two months by this combined method of treatment.

In the cases above referred to the administration of insulin was reduced to once a day only at the end of a fortnight. The diet was gradually increased, according to the individual requirements, and the drugs were gradually reduced till the patients passed a sugar-free urine on a diet of the approximate value of 150 grm. of carbohydrate. When the insulin was finally withheld altogether there was a re-appearance of a little sugar in two or three of the cases. This, however, was readily adjusted by slightly diminishing the carbohydrate intake. As long as patients keep to a reasonable diet and take sufficient care of themselves there is no doubt that they can pursue their ordinary vocation like other people who are free from the disease. Such people can answer to those that desire to know—does insulin cure diabetes? Yes, it does cure the careful man.

The disease persisted for a longer time in the cases that were treated with insulin alone until the combined method was adopted, when equally satisfactory results were obtained.

After some time there were a few recurrences, and on investigation it was found that these patients had, by various means, taken three or four times more carbohydrate than their recently gained capacity permitted.

Diabetics have such a craving for carbohydrate foods that they seem unable to resist the temptation. These form the majority of the people who swell the ranks of the pessimists who fail to see the benefits of this valuable preparation. Optimists and opportunists do or do not want to see that at least fifty per cent. of the cases in Ceylon are amenable to ordinary treatment without insulin. This fact, however, does not minimize the value of one of the most important discoveries of this century.

Colonial Medical Reports.—No. 174.—Bihar and Orissa.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF BIHAR AND ORISSA FOR THE YEAR 1923.

Periodicity in Disease.

There is undoubtedly a periodic function of epidemic and infectious diseases, but it is difficult to define and is masked by many other influences which affect the prevalence of such diseases. It may be noted that some diseases, such as plague and small-pox, are more regular in their recurrence, whereas malaria and cholera, which depend more upon favourable climatic conditions for their epidemic spread, are more irregular. It appears, however, certain that each violent epidemic is followed by a corresponding reaction in which the disease is much less prevalent than ordinarily, and that if local and other influences could be eliminated, or allowed for, it would probably be possible to define accurately the periodicity of each disease. Each epidemic disease appears to have a different cycle of recurrence, the periodicity of which is based upon the immunity created in the population by the epidemic prevalence of the disease itself. In short it appears that the problem is fundamentally one of immunity, and that the periodicity of epidemic diseases depends upon the degree and the duration of the immunity which results from the general prevalence of the disease.

Epidemicity.

Epidemicity is, from the public health point of view, the most important and most characteristic property of many infectious diseases. We know that certain diseases can become widespread and severely epidemic with great rapidity. We know a good deal about the diseases themselves, but we know very little about the conditions which make them suddenly and severely epidemic and which often with equal suddenness cause the epidemic to subside.

Each disease has an epidemicity of its own, which may be defined in mathematical terms as a function of the disease itself, which is probably constant. This epidemicity factor in some cases is very small, e.g., in leprosy, whilst in diseases such as cholera it is very large. The rapidity of the spread of a disease in epidemic form varies directly with the epidemicity factor, but is, of course, also affected by other factors. When the epidemicity factor is large, as in cholera, the logical conclusion would be that the entire population would be stricken, but what we actually find is that "one is taken and another is left." The disease spreads rapidly, but fails to affect a large number of the population. That failure is not due to human intelligence nor human effort, which are minor factors in the bulk of the population. It is also not purely nor even largely accidental, which is obvious on mathematical grounds. The phenomenon is too regular and certain in its occurrence to be due to any other than a direct cause. Hitherto the observed facts have been known but not understood. The recent work of d'Herelle has made clear the cause and has definitely linked up the periodicity and epidemicity of disease with immunity, by showing how nature has made and controls the balance between the human organism and infectious diseases, and how the "bacillus" is held in check and prevented from multiplying indefinitely, and at the expense of the human population.

Comparative Incidence of Chief Diseases.

The death-rate for the year was less than the average of the last ten years, and there was a marked reduction in the incidence of all epidemic diseases, especially fevers and cholera.

The infectious diseases, the spread of which largely depends upon overcrowding, density of population, and the consequent facilities for infection, are consistently more prevalent in the towns, whereas fevers, of which malaria is the chief, are more prevalent in the rural areas, where the facilities are greater for the breeding of anopheline mosquitoes and where the economic condition of the people is frequently not so good.

The large towns are hot beds of consumption, and this disease, together with pneumonia and influenza, causes the death-rate from respiratory diseases to be many times greater in towns than in rural areas. Similarly, cholera and plague are more prevalent in the towns than in the villages.

Cholera Preventive Measures.

Special preventive measures were taken, and a special staff was employed as usual. The use of chlorinated lime for disinfecting wells has now been generally adopted by local bodies and the procedure is generally known and appreciated.

A special epidemic cadre of ten assistant surgeons was maintained. The headquarters of the cadre were at Patna, and these officers were sent out on epidemic duty throughout the province whenever epidemic disease was prevalent. They were employed on plague duty in Bihar, and cholera duty at Puri and in Orissa and Bihar, and at other times they were employed in carrying out some investigation work.

A special epidemic reserve of one hundred vaccinators was also maintained from April 1 to the

end of September for cholera and other epidemic duty.

These men received a few days training in the use of disinfectants and in the disinfection of wells, and were sent out by the civil surgeons with disinfectants and a few simple remedies whenever cholera was reported.

During the year, a new scheme for a simple and cheap organization for preventive measures against cholera and other epidemic diseases was issued to all local bodies and it is proposed that this scheme should be taken up as far as funds permit.

At the same time, a leaflet on "Simple Instructions for the Prevention of Epidemic Diseases" was issued to all local bodies, the Press and many Government Departments, and many District Boards and Municipalities have reprinted this leaflet in vernacular and distributed it broadcast through schools, sirpunches and other local agencies.

Cholera is a preventible disease and the only source of infection is human excreta. The cholera germ does not live long outside the human body, and if it can be killed by disinfection as soon as it appears upon the scene, we can largely prevent the spread of the disease.

As it is, the transmission must be rapid from the excreta of one case to the body of the next, and that this is so is illustrated by the rapidity with which epidemic cholera sweeps through a town or district. It is, therefore of primary importance to deal with the source of infection promptly and thoroughly in order to prevent the spread of the disease. This means that disinfection of the excreta and of all contaminated things must be done without delay. If this is done, the disease cannot readily spread, because there is very little chance for the infection to get into water, wells or food, or on to flies, or people's hands. The time factor here is the all-important consideration. Every second's delay means risk, and much delay means failure.

The epidemic prevalence of cholera is largely associated with the prevalence of flies, and good conservancy and the rapid removal and disposal of excreta are fully as important measures for the prevention of cholera as the provision of pure water supplies, and both these preventive measures should be widely adopted, especially in towns, if cholera is to be kept in check and ultimately stopped.

Small-pox.

The death-rate fell in seven out of twenty-one districts. It is well-known that vaccination is the best and the only real means of prevention of small-pox, and yet vaccination is neither compulsory nor free. There is no doubt but that the cost of vaccination work is a splendid and profitable investment of public funds, which can save many lives and much sickness and suffering. It would, therefore, appear to be wise and proper to organize the work more effectively and to make vaccination compulsory and free, in order to get the whole population protected and thus abolish a disease which is of all diseases the most easily and cheaply preventible.

The manufacture of vaccine lymph and the organization and staff for vaccination work are all at present arranged for by Government, and facilities are available throughout the province for getting the operation performed by trained vaccinators with pure vaccine.

Fever Statistics.

There was a fall in the rate of mortality under this head in five districts. The highest mortalities were recorded in the districts of Purnea and Palamau, and amongst towns in Kendrapara, Gaya, Jagadispur and Purnea.

Mortality from fevers is an "omnibus" return which includes a large number of pneumonia cases, kala-azar, phthisis, typhoid and, in short, all diseases of which fever is a symptom. In my experience malaria is not an ordinary cause of much mortality in most of the districts of Bihar, and I agree with the opinion recently expressed by the Public Health Department of the United Provinces that malaria is only responsible for a small proportion of the deaths from fevers. The recent investigation into the details of vital statistics in a selected area in Bengal also supports this view, and I think it may be stated as more than my personal opinion that, with the exceptions of particular areas and of epidemic invasions, malaria is not an important cause of mortality in the province of Bihar and Orissa, and that therefore the occurrences of epidemic malaria or influenza may be accurately estimated by any abnormal increase in the reported mortality from fevers.

Malaria in Bihar and Orissa.

The economic importance of malaria as a cause of debility, ill-health and ultimate mortality throughout the province is, however, great. The disease is endemic throughout the province, though to a varying degree in different districts, and it tends to become often epidemic in localized areas where the conditions are favourable to its transmission, and to become generally epidemic over larger areas at intervals. The year under report was a phenomenally healthy year owing to the prosperity and favourable climatic conditions which prevailed, but the disease was prevalent in epidemic form in Balasore and Cuttack districts and began to spread into the district of Puri. Similarly it was very prevalent in several parts of Chota Nagpur, especially in Singhbhum and parts of Ranchi district.

In my opinion it is not practicable to prevent malaria, or to reduce it permanently or on any large scale, by the use of quinine. The quantity of quinine required does not exist, and if it *did* the people would not swallow it. Quinine is essentially a drug for the treatment of malaria as a disease, but it is not a means of stamping out the disease, nor of preventing it on a large scale under existing conditions.

Colonial Medical Reports.—No. 174.—Bihar and Orissa (*continued.*)

The adoption of non-productive and anti-malarial operations such as draining, levelling, filling hollows and oiling water surfaces is also not a feasible means of prevention on a large scale over an enormous area. The staff which would be required to carry out such works and to maintain them would be enormous, and the expense would be colossal and prohibitive. It is, therefore, in my opinion, a waste of time to discuss and to advocate the use of such measures, except in special cases.

What is wanted is a policy of malarial prevention which will pay its own way and can be carried out in conjunction with other work of a productive nature. The people might then be expected to take up such work individually in their own interest, and the collective result of work carried out by countless workers throughout the province would be definite and more permanent. Further, such a policy would at the same time improve the economic condition and the prosperity of the people and would indirectly also reduce the prevalence of all epidemic diseases by making the people healthier and stronger.

Such a policy is possible: it is already being carried out in Italy and Spain with extraordinary success. It consists in combining agricultural improvement with sanitation, by draining or flooding marshes and wet lands in a scientific manner so as to produce larger crops, and at the same time to reduce the breeding of transmitting mosquitoes and the spread of malaria. It also includes the cultivation of waste lands as far as possible and the intensive cultivation of good lands.

Sir Edward Buck, K.C.S.I., wrote a most interesting report on this subject in 1907, and recently the question was again raised by Mr. Inglis, who sent to the local Government a number of extracts from recent Italian literature.

This policy is possible and it is productive. It improves the health and the prosperity of the people at the same time, and the more their health is improved the more land can be brought under cultivation and so the results are cumulative and progressive.

Sale of Quinine.

The sale of quinine treatments during 1923 amounted to a total of 1,027·6 pounds of quinine sulphate as compared with 639·1 pounds in the previous year. The increase is due to increase in the prevalence of fevers in some of the Orissa districts and also to the increased prosperity of the people, which has created a much large purchasing capacity. Quinine was chiefly sold through the agency of postmasters, and to a slight extent through other agencies. Owing to the increase in the wholesale price of quinine during the last few years, it is now under consideration to supply cinchona febrifuge instead of quinine for retail sale throughout the province, as this drug is quite effective in treatment and can be sold at half the price of quinine.

Plague Statistics.

The provincial death-rate from plague was ·8 as compared with ·4 in the previous year. More or less regular recrudescences of plague occur at periodic intervals of about four years. The disease has not shown any marked tendency to spread outside the epidemic area, and it appears to be slowly diminishing in virulence and in prevalence with the lapse of time. The recrudescence of plague which occurred during 1922-23, five years after the previous periodic increase was followed, as was anticipated, by a further diminution in the incidence of plague during the cold weather of 1923-24.

Dysentery and Diarrhœa.

The death-rate from dysentery and diarrhœa was ·5 as compared with ·5 in the previous year. As usual, this disease was most prevalent in the Orissa Division and of the total deaths, amounting to 18,788, this division reported 14,249.

These diseases resemble cholera in their nature and in their incidence. They belong to the group of intestinal diseases, the transmission of which is associated with the infection of the individual by be effected by the improvement of water supplies, by excreta, or of food by flies. They tend to become epidemic under the same conditions and by the same means which favour the spread of cholera and their prevention, like that of cholera, can best be effected by the improvement of water supplies by better conservancy and by prompt disinfection of the excreta of the sick. The effects of introducing piped water supplies in the towns of Gaya and Bhagalpur were that the death-rates from cholera, dysentery and diarrhœa were immediately reduced to about half of what they had been in previous years, and they have since remained at the lower level. This means an average saving of 700 lives from these diseases, chiefly the lives of children, in these two towns alone, every year.

Hookworm.

The prevalence of hookworm infection, and the importance of the disease, both as a predisposing factor in the prevalence of other diseases, especially intestinal diseases and malaria, and as an economic factor of great importance in the productive capacity and prosperity of the population have attracted considerable attention in recent years. Investigation work has been carried out in other provinces as well as in Bihar and Orissa.

In Bengal, a special staff was employed for two or three years and it has been shown that approximately two-thirds of the population of Bengal are infected with hookworm. In the United Provinces the prevalence of the disease varies in the different parts of the province, but is greatest in the Gangetic districts adjoining this province in which over 80 per cent. persons examined were found to be infected. In this province investigation has been

carried out which has shown the general prevalence of the infection, varying from fifty per cent. upwards to over 75 per cent. of the persons examined

There is, therefore, no doubt about the existence of the disease, and the slight variations in its prevalence are immaterial. The importance of the disease, both from the health and the economic points of view, is best demonstrated by the experience of the results of anti-hookworm campaign work in tea gardens and in America. The results are immediate and definite. There is a marked improvement in the health and in the working capacity of the population which it is difficult to appreciate until it is seen, but which, when seen, at once convinces the observer, as it has already convinced the population which has been treated.

The disease is easily and rapidly curable within a few days, in the majority of cases, and the patient who was previously unaware of illness, but who suffered from enfeebled health and diminished vitality and vigour, immediately begins to feel better, stronger and more vigorous. The prevention of this disease entails both the treatment of infected persons and an alteration in the habits of the people, requiring them to abandon the general practice of relieving themselves in the fields, and to take to the use of latrines in order to prevent the continuous and rapid re-infection of the population from the soil.

The curing of infected persons and the prevention of the disease by removing the means of infection, as above indicated, can both be accomplished in time, but not immediately. The cost of such measures on a large scale would be enormous and can only be met, as in the case of preventive measures against other diseases, by an improvement in the economic condition of the people. With regard to this disease also, we are again faced with the general proposition that the prevention of disease is very largely an economic question, and that unless it is considered and attacked from that point of view, little or nothing can be done to deal with it.

The latest work on this disease indicates that heavy infection is necessary to give rise to special symptoms and that local conditions of overcrowding and general filth, such as contained in construction works, mines, &c., where coolies are temporarily collected in large numbers, give rise to a heavy infection of the soil and a corresponding subsequent heavy infection of the population. The number of eggs passed by one infected person is enormous, and the cumulative effect of repeated infections produces marked debility and anæmia. Beta-naphthol, thymol, and carbon tetrachloride appear to be the most reliable drugs for treatment, but it must never be overlooked that treatment alone is largely a waste of time. The use of latrines and general cleanliness, and in cases where a heavy soil infection exists the disinfection of the surface soil in and adjacent to the houses is necessary if the disease is to be dealt with effectively.

Colonial Medical Reports.—No. 175.—Colombo.

REPORT OF THE MEDICAL OFFICER OF HEALTH FOR COLOMBO FOR THE YEAR 1923.

THE health of the city as gauged by the amount of sickness and the mortality was not satisfactory. The crude death-rate was 35·5. At the time the census was taken Colombo had not fully recovered from the effects of the war and a great part of the large immigrant population, which had left the town during the war, had not returned, so that the population figure obtained at the census was considerably below the true figure.

Conditions have now changed, trade is flourishing, prosperity is returning, and with it those who left the town and also fresh immigrants in search of employment, so that the population of 300,924 obtained on the basis of the estimates prior to 1921 may be taken as nearer the mark than 250,433 obtained on the basis of the census population of 1921. The death-rate calculated on this population, i.e., 300,924, is 29·6 per thousand and 25·9 per thousand, exclusive of the deaths of non-residents.

The unusual weather conditions that prevailed last year were, no doubt, mainly responsible for the increase of the death-rate over the previous year, but, apart from this, the average death-rate from phthisis, pneumonia, enteric fever, and infant mortality, is still very high. The principal causes which maintain these death-rates at a high level are bad housing conditions under which the poorer classes live, the bucket-latrine system, bad drainage, and poverty.

Of all the problems the municipality is faced with the one dealing with the housing of the working-classes is the most important and urgent. The great wastage of human life, not to speak of the suffering and loss of efficiency occasioned by disease, that takes place every year imperatively demands the earliest attention to this problem. No satisfactory reduction in the general death-rate could be expected so long as a considerable proportion of the population lives under conditions most favourable to the generation and spread of disease and most inimical to health and life. There are other problems, too, awaiting solution, such as infant mortality, malaria, adulteration of food,

drainage, &c., but in order of importance the question of housing comes first.

Anti-Mosquito Work.

Weather conditions last year were most favourable for the breeding of mosquitoes, and consequently a very large number of complaints was received from all parts of the town. Queen's House was also badly invaded, and on investigation many of the gutters of the buildings in its vicinity were found to be breeding mosquitoes. The species found were chiefly stegomyia and culex, with a few migratory species. No malaria-carrying mosquitoes were found. In the great majority of cases, blocked or badly-sloped gutters were found to be the chief breeding places.

In addition to attending to complaints, the staff was engaged in its routine of house-to-house inspection in the residential area.

The number of complaints received by this department has been steadily increasing. The public, with a few exceptions, take no interest in mosquito prevention and expect the Public Health Department to do everything for them. With the very small staff of one sub-inspector, six overseers and twelve coolies, it is impossible to inspect all the premises in the town, and to destroy the breeding places. What is needed is legislation making householders and owners of property responsible for preventing the breeding of mosquitoes on their premises.

Births.

There were 7,107 births registered during the year. The rate is higher than that of 1922, but lower than those of 1920 and 1921, when the unusually high birth-rates, as pointed out in previous reports, were recorded.

Deaths.

There were 8,893 deaths registered during the year. It is rather disquieting to record that the crude death-rate for the year was higher than that of any other year of the decennium, but as explained under the section dealing with population, the rate cannot be relied upon as it was calculated on a population much lower than the actual, and if it had been calculated on the estimates prior to the taking of the census, the rate would have been reduced to 29·6, a quite satisfactory one.

Pneumonia is still the prime contributory cause of the general death-rate, due to a great extent to the prevalence of influenza.

Infant Mortality.

Total deaths, 1,929.

The principal causes of death were convulsions, atrophy and debility, diarrhœa, premature birth and pneumonia.

Infectious Diseases.

Notifiable infectious diseases reported during the year were plague, cholera, small-pox, chicken-pox, continued fever, phthisis, scarlet fever, typhus fever, continued fever, phthisis, scarlet fever, typhus fever, totalling 4,836 cases.

Pulmonary Group of Diseases.

Under this heading are included pneumonia, phthisis and bronchitis, of which only phthisis is notifiable.

(*a*) *Pneumonia.*—Deaths, 1,251.

Pneumonia is one of the most fatal of all acute diseases; it claimed the highest number of deaths during 1923; 14 per cent. of all deaths in Colombo were due to this disease. It was prevalent throughout the year with a marked increase during the first five months, and again in the month of September. Pneumonia is an infectious disease which is spread from person to person through the secretions of the mouth and nose, and overcrowding naturally favours contact infection. Its excessive prevalence in Colombo is due to a large porportion of the inhabitants living in overcrowded, ill-ventilated, stuffy rooms, and to other predisposing causes, such as chills, exposure, dusty atmosphere, poor and insufficient food, alcohol, and anything that tends to lower the vitality. Influenza was again undoubtedly responsible for the increased mortality.

(*b*) *Phthisis.*—727 deaths. Naturally, the most crowded and insanitary areas of the town show the largest number of cases. Next to pneumonia, phthisis claims the highest number of deaths. In Ceylon the disease is mainly spread from man to man through direct association; infection through infected milk is practically unknown. It is a disease fostered by overcrowding, bad lighting and ventilation of living rooms, dust, &c., and nine-tenths of the tenement dwellers of Colombo live under these conditions. Improved housing conditions diminish the incidence of phthisis by reducing the chances of contact infection, providing more light, purer air and sunshine in houses, and generally raising the standard of cleanliness. Other measures are also necessary, such as early diagnosis and notification, segregation of sick, proper disinfection and disposal of sputum, medical inspection of workmen in factories, education of the public, the after-care of cured cases, &c. Many cases which have improved under treatment or been completely cured and discharged from hospital or sanatorium return to their wretched homes to get re-infected and die. The most important preventive measures therefore are: the improvement of the housing conditions, and the after-care of patients. With the steady increase of population, the housing problem becomes aggravated and more and more difficult to solve and the poor are hard put to it to find any kind of accommodation within a reasonable distance of their work places.

Dust is another important factor in the spread of phthisis: in the districts in which the poor live the streets are deep in dust, and it is not only a nuisance, but a serious menace to the health of the people.

(*c*) Bronchitis.—Deaths, 188.

Bronchitis shows a decrease compared with the previous year.

Influenza.

317 deaths were registered.

Judging from the number of cases treated at the Municipal Dispensaries, the disease was prevalent throughout the year, with a rather marked increase in the months of May and December. Influenza is highly infectious in the early stages, and as most people regard it at first as a common cold and go about their daily routine even during the febrile stage, the infection becomes widespread, especially as one attack of the disease seems to predispose to subsequent attacks. The control of the disease rests mainly with the public; if the first case in every household is properly isolated and the patient stays in bed without going about broadcasting the germs, the disease would not become so widely prevalent. Neglect or exposure to cold and wet during the febrile stage, or before the catarrhal symptoms have completely disappeared, is generally dangerous, and when pneumonia supervenes the disease usually ends fatally. Influenza was undoubtedly responsible for the increased mortality from pneumonia.

Diarrhœal Diseases.

Under this heading are included diarrhœa, enteritis, and dysentery, none of which are notifiable.

The total deaths from all these causes were 990, diarrhœa and enteritis 681 deaths, and dysentery 309 deaths.

These diseases are associated with flies, overcrowding, lack of cleanliness and other unhygienic conditions, all of which are usually present in the slum areas, and which were aggravated by the weather conditions of last year. Owing to the epidemic of rinderpest, dung could not be regularly removed from dairies and cattle sheds, and consequently flies, which play such an important part in the spread of enteric, dysentery, &c., by contaminating food, were exceptionally prevalent throughout the year. In addition, the refuse destructor was out of commission for some time, and all refuse was dumped within the town in the swampy land near the destructor, and this undoubtedly provided an excellent breeding place for flies. Also, the exceptionally wet weather led to increased overcrowding, accumulation of organic refuse, pollution of soil, neglect of private premises and bucket latrines—conditions favourable to the generation and spread of these diseases.

Fevers.

Under this heading are included enteric fever, continued fever of over seven days' duration, and remittent and intermittent fevers, of which only the first two are notifiable.

Enteric Fever.—741 cases; 269 deaths.

As usual, the crowded insanitary areas of Kotahena and Maradana Wards were chiefly affected. As stated in the section dealing with diarrhœal diseases, flies were exceptionally bad last year, and the general sanitary conditions of private premises and bucket latrines was, on the whole, unsatisfactory, and these conditions were undoubtedly responsible for the increased number of cases. Cases are notified often so late as to make preventive measures practically useless. See explanation for this under section dealing with continued fever.

Continued Fever.—Total cases, 110; deaths, 37.

The majority, if not all, of the fatal cases were probably cases of enteric fever which had been seen, perhaps only a few days before death by the medical practitioner reporting the case. All the fevers which are not definitely diagnosed are usually reported under the convenient term of continued fever, and the real nature of the disease remains unknown.

Malaria.—Deaths, 166.

Malaria was unusually prevalent throughout the island last year.

Early last year, in a house in Alston Place, six cases of locally-acquired malaria, microscopically confirmed, were brought to the notice of this department, and on investigation two chronic malarial subjects were found living in the adjoining house. On search being made for mosquito breeding places, *Anopheles sinensis* was found breeding in a pit in the adjoining premises, and in a pool in the reclaimed part of the Hunupitiya end of the lake. An adult *Anopheles listoni* was caught in the patient's bungalow, but its breeding place, though carefully searched for, was not discovered.

Another case of locally-acquired malaria was reported from Horton Place, and on investigation, *Anopheles sinensis* was found breeding in the swampy land at the junction of Horton Place and McCarthy Road. All these breeding places were abolished, and no further cases were reported from the Cinnamon Gardens district.

2,411 cases of malaria were treated at the four Municipal Dispensaries during the year. In the case of 1,932 of these, there was a definite history of infection acquired outside Colombo. As regards the rest, 432 cases were not traced, as false addresses had been given at the dispensaries, and in 43 the infection was believed to have been acquired in Colombo. These cases were not microscopically confirmed, and it is possible that all were not malaria and all were not infected in Colombo, as several of these cases, particularly the Modera and Rajamalwatta ones, had been on pilgrimage to shrines in malarial districts, and had probably acquired infection there. In the case of some, the evidence seems to be in favour of local infection. The majority of these cases occurred moreover in the neighbourhood of swampy grassfields where mosquitoes are always bad, and where *Anopheles rossi* was found in large numbers, but the part this species plays in transmitting malaria has not been fully worked out. In the districts in which these cases of malaria occurred, numbers of people harbouring the malaria parasite live. They are, for the most part, workmen who have returned to Colombo ill with malaria acquired in the various new railway extensions in the island

Colonial Medical Reports.—No. 175.—Colombo (*continued*).

These carriers are important factors in spreading the infection, and are a distinct danger to the town, because they increase the foci of infection within the town. Known malaria carriers such as *A culicifacies*, *A. listoni*, and *A. sinensis* have been found breeding within the town. We do not yet know definitely whether *A. rossi*, which is found in such large numbers in the town, is an effectual agent in the transmission of the disease, but if it proves to be so, Colombo, with its extensive swamps within and around it, and with no anti-mosquito legislation, will be faced with a very serious problem.

PLAGUE.

Human Plague.—There were 230 cases with 209 deaths.

The marked increase above the average which began in December, 1922, was maintained till the end of February, when there was a marked drop, the weekly incidence during the first three weeks of March and again the number of cases went up, and kept above the average, practically right through the off-season with a well-marked increase in August and September. An unusual feature was the comparatively large number of rat and human plague cases during the off-season.

Last year's abnormal rainfall, associated with a low atmospheric temperature and high humidity was undoubtedly responsible for the large number of cases of plague during the normal off-season. It is especially noteworthy that the proportion of *Xenopsylla cheopis*—the special plague-carrying flea found on rats—never fell below 9·49 per cent. Dr. Hirst is of opinion that the number of *X. cheopis* was abnormal throughout the off-season of plague, and the increase more pronounced than usual in November and December. He attributes this increase to the abnormal weather conditions which were favourable for the multiplication and survival of *X. cheopis*.

Of the 230 cases of plague, 66 were septicæmic and 164 were bubonic. As statement 40 shows, since 1920 the proportion of bubonic cases to septicæmic cases had been gradually increasing, and last year it was the highest. From 1914—the year of outbreak of plague in Colombo—to 1919, the proportion of septicæmic cases of plague was higher. Dr. Hirst thinks this is due to a gradual lowering of the virulence of the Colombo strain.

As usual, males between the ages of fifteen and twenty-five were chiefly attacked.

Rat Plague.—29,312 rats were examined at the Municipal Bacteriological Laboratory, and 153 were found to be infected. The vast majority of rats which become infected die in their underground runs, and the number of infected rats known represents only a microscopic minority of the number which die. There was an outbreak of rat plague at the Customs in the month of May, when 29 dead rats were found in a block of warehouses; 27 of these rats were found on bacteriological examination to be plague-infected; the other two were mummified and unfit for bacteriological examination, but had undoubtedly died of plague. Twenty-one live rats were killed, but they gave a negative result for plague.

One cat and one squirrel were found plague-infected during the year. The cat was found dead near a plague-infected house, and the squirrel was found in a house where there were several cases of rat plague.

Rat Destruction.—Altogether 137,645 rats were accounted for during the year, of which 133,684 were caught in traps, 642 were found dead (283 of these were in a mummified condition), and 3,319 were killed by the Clayton fumigators and their bodies recovered.

1,693,285 poison baits were placed, of which 80,296 were eaten or removed by rats. It is impossible to estimate the number of rats that are killed by these poison baits, or by the fumigators, as it is not possible to trace and open up all the innumerable rat-runs without seriously damaging the building and interfering with trade, but it is believed the number so killed is very large.

Preventive Measures.—The same preventive measures as hitherto were carried out during the year.

SMALL-POX.

There were thirty-two cases of small-pox and one death during 1923.

CHICKEN-POX.

There were 1,315 cases, including four from the Port, and seventy-six from outside town limits. There was one death, that of an infant fifteen days old, brought to the Infectious Diseases Hospital from an out-station.

The disease was most prevalent during the first five months of the year.

MEASLES.

Measles again assumed epidemic proportions after an interval of three years. The last epidemic was in 1920, when there were 1,062 town cases. During the year under review the highest number of cases was recorded during the month of March.

The total number of cases was 789. Of these, 471 cases were of children under ten years of age, 128 of children under fifteen years of age, and 190 persons over fifteen years of age. There were sixteen deaths, all of children under ten years of age.

DIPHTHERIA.

There were nineteen town cases and eight outside cases during the year with seven deaths. Of the twenty-seven cases, twenty-one were of children under twelve years of age, four of children under sixteen years of age, two only of adults.

MISCELLANEOUS DISEASES.

Leprosy.—Three cases of leprosy were reported by the Public Health Department to the Principal Civil Medical Officer during the year for action to be taken under the Lepers Ordinance, No. 4 of 1901. Two of these cases were of the anæsthetic

type, and the other one was of the tubercular type.

Tetanus.—Total, fifty-nine deaths; fifty-two adults and seven infants.

Syphilis.—83 deaths; twenty-four adults and fifty-nine infants.

There were no cases of cholera, scarlet fever, typhus fever or beriberi.

Investigations on the Control of Hookworm Disease.

Previous annual reports contain references to the remarkable outbreak of hookworm disease, which occurred in May, 1919, among a gang of coolies engaged in digging out a new set of trenches at the Northern Sewage Treatment Works.

The coolies developed dermatitis wherever their bodies came in contact with the soil of these trenches. Close inquiry was made into all the circumstances by Dr. Marshall Philip and the Ceylon Sanitary Commissioner, but no other source of infection could be traced than the septic tank sludge buried in the trenches at least two years previously. Numerous larvæ closely resembling, if not identical with, hookworm larvæ were found in the suspected soil.

At that time the tanks were unmodified. Sedimentation was very inefficient, the contents of the tanks being kept in a constant state of ebullition by the escape of large volumes of the gaseous products of the excessive fermentation which takes place in septic tanks at tropical temperature.

Hookworm ova and larvæ are carried through septic tanks in this condition in a few hours, and continually pass out with the effluent or with the uppermost layers of the sludge at each opening of the sludge valves. Owing to the danger thus disclosed the proposal to sell the sludge as a valuable manure had to be abandoned.

The question of the viability of hookworm ova and larvæ in soil also arose in connection with the safe disposal of the fifty-acre night-soil burial ground at Narahenpita.

For more than twenty years night-soil representing the fæces deposited by a population of some 200,000 people had been buried in these fields.

In 1922 the Water Carriage Sewerage Scheme was sufficiently completed to enable the depot to be closed so that the land became available for other purposes.

On August 17, 1922, another remarkable outbreak of hookworm dermatitis occurred amongst a gang of eight coolies engaged in clearing the sump of the Maligawatta Pumping Station.

It is hoped to report the full details in a medical journal, but a brief summary of the circumstances is given here.

In order to clear out the sump the nearly naked coolies immersed their bodies in the semi-liquid sludge, one at least up to his neck. Within half an hour all eight men were complaining of intense irritation of the skin, which increased to the extent of disabling them for duty on the following morning.

The writer saw these men on the evening of the second day and diagnosed the condition as hookworm dermatitis. The eruption was co-extensive with the area of each man's skin that had come in contact with the sludge. The sludge itself was found to contain typical hookworm larvæ in addition to numerous larvæ of other nematodes.

The coolies were handed over to Dr. J. F. Docherty, the Ceylon Director of the Ankylostomiasis Campaign. Most of the men were already lightly infected with hookworm. They were treated till free from ova with carbon tetrachloride and guarded as far as possible from reinfection. About eight weeks are usually required for the larvæ to reach the intestine from the skin, mature, and pass into the bowel. The coolies were examined for ova at intervals and finally on the ninety-first day the worms were expelled with a full dose of carbon tetrachloride, followed by salts. The species of worm was *Necator americanus*.

The worms expelled may be taken to represent 98 per cent. of those actually present. The number of worms recovered was perhaps less than might be expected from the degree of dermatitis. It is an interesting speculation to what extent the penetrative larvæ of domestic animals may have been responsible for some of the dermatitis.

According to Brumpt many such larvæ are capable of penetrating the human skin and setting up inflammation, though unable to establish themselves in the human intestine.

The results are evidence of a new danger to the health of the labour force engaged in a tropical sewage works. Several other isolated examples of hookworm dermatitis among coolies engaged in clearing sumps or septic tanks have subsequently occurred.

It clearly became necessary to inquire into the following:

(1) How many hookworm eggs were contained in an average mass of fæces passed into the sewers or deposited in the trenches at Narahenpita.

(2) What proportion of these eggs could be hatched out in sewage or beneath the soil.

(3) How far can the infected larvæ ascend to reach the surface through typical soils.

(4) How long can these larvæ survive in these soils or sewage under the most favourable conditions likely to be met with in Colombo.

Some preliminary work on these problems was begun in this laboratory in 1920, shortly after the writer's return from war service, but it was not till the International Health Board of the Rockefeller Foundation assisted us with a grant of funds in August, 1922, that any serious attempt could be made to tackle these problems in the field or in laboratory

The results of investigations on the lines outlined above will be applicable to the control of hookworm disease in other islands in the tropics in due proportion to the similarity between their soils and climatic conditions and those of Ceylon.

General conclusions regarding the epidemiology

of hookworm disease should be based on a comparison between accurate observations made in a variety of stations in the tropic zone. Similar problems are being investigated under the auspices of the Board on somewhat similar lines in various other parts of the world, particularly in Trinidad and Porto Rico. A series of reports from American observers have recently appeared in the "American Journal of Public Health."

In what follows an attempt will be made to briefly consider the more important phases of the inquiry and to show what is being done to throw light upon the problems at issue.

Egg Output.—The degree of hookworm infestation of the sewage works and the Narahenpita trenching ground depends primarily on the number of female hookworms harboured by the population of Colombo.

The number of eggs passed in the fæces per female hookworm is a variable quantity. Recent research by Stoll using his recently introduced technique puts the figure at about 9,000 per diem.

The writer has devised a method for roughly estimating the average output of viable eggs by the people of the city. It is based upon counts of the number of larvæ cultivated per gramme from a representative mass of night-soil.

Now that the results of the cultivation technique can be checked by accurate egg counts, it would seem worth while to apply this method to complete the results obtained from the hookworm survey of the town organized by Dr. Marshall Philip in 1919.

According to the results of this survey 40 per cent. of the general population of the town are infected with hookworms, i.e., there are about 100,000 people continually discharging hookworm eggs within the city limits.

The true measure of the degree of hookworm infestation of a population is the average number of worms per individual, i.e., the worm index. Darling has worked out a technique for ascertaining the worm index of population groups, but it is extremely laborious and only accurate if the group is for the time being under full control of the observer. Assuming a worm index of only one per inhabitant, the number of eggs formerly buried each day at Narahenpita would exceed one thousand million. The number now passing into the sewers is certainly not less.

548 of the positive cases found in the course of the survey were clinically examined, 279 showed no symptoms at all of hookworm disease, 222 were slightly anæmic, 46 were evidently anæmic and exhibited marked signs of hookworm disease.

No uniform relationship exists between severity of symptoms of ankylostomiasis and number of hookworms harboured by a particular individual. The presence of a few worms is sometimes associated with marked signs of disease in individuals exceptionally susceptible to the worm toxin; on the other hand, several hundreds of worms have been borne without apparent effect upon the health and energies of their host.

The data obtained in recent surveys in America indicate that where no other anæmic-producing disease is prevalent, such as malaria, the sub-division of the infected population into groups on the basis of the clinical signs corresponds with the grouping according to number of worms carried and egg output. The worm index of a group showing recognizable signs would be upwards of fifty. An index of 1,000 represents a very heavy infestation likely to be associated with severe or even fatal illness. The incidence of malaria in Colombo is insignificant. Ankylostomiasis is the only notable prevalent anæmic-producing disease, so that we are justified in inferring from the clinical results of the survey that the worm index must be low.

The number of viable eggs per gramme of night-soil from a latrine at Wellawatta corresponded roughly to a worm index of ten.

Egg Hatching.—The essential requirement for egg hatching seems to be a sufficient supply of oxygen in the hatching medium. In the absence of oxygen hookworm eggs do not develop. How long can they remain viable in a favourable anærobic medium is still unknown.

Till recently it was generally supposed that eggs buried in a few inches of soil or discharged into a sewer or cesspool would be unable to develop. The writer buried fæces containing numerous hookworm eggs at various depths up to three feet under soil from the Madampitiya and Narahenpita trenching grounds and under ordinary cabook. If the fæces were well mixed with the soil at the bottom of the pit abundant larvæ were developed, but if masses of fæces were simply covered over development only took place on the surface of the fæcal mass. Similar results have recently been obtained in the West Indies. The comparative failure of raw fæcal cultures has been noted by American observers and attributed by them to the development of high acidity. The more vegetable the diet the greater the acidity, and the fewer the larvæ hatching out. It would seem therefore that only a small proportion of the ova buried in night-soil at Narahenpita would be in a position to develop into larvæ.

The conditions found at the sewage works are also unfavourable to the hatching out of hookworm eggs. In the laboratory eggs deposited at the bottom of flasks containing crude sewage or septic tank liquors failed to develop if air was excluded from the flasks. The development which took place in the sump of the Maligawatta pumping station and subsequently in the sumps of other pumping stations is probably to be attributed to the proximity of a ventilating shaft passing down to the sewer close to the pumping station. Moreover, several of these pumping stations are close to the "tipping depots" where night-soil is tipped on to screens and flushed into the sewers so that a concentrated dose of fresh ova must enter the sumps each day.

Borland McVail found hookworm eggs and larvæ in the effluent of nineteen out of fifty-six septic tanks in Bengal sewage works. These tanks were

unmodified. They are now being reconstructed by the authorities in Bengal with a view to reducing gasification and obtaining improved sedimentation. Ova in unmodified tanks are not only constantly brought to the surface and given access to oxygen, but rapidly carried through into the effluent.

The work of reconstructing the tanks at the northern treatment works, begun in 1915, was finished in 1920. Few larvæ now pass through the modified tanks, only one was found in thirty litres of effluent, and none in fifteen kilogrammes of sludge. It is not possible as yet to be so definite as regards ova. No other worm likely to be met with in the human intestine produces eggs resembling those of hookworm, but the worms of certain nematodes parasitic in domestic animals lay similar eggs, which are difficult to distinguish from those of human hookworm and liable to be found in sewage.

Larval Growth.—After hatching from the egg hookworm larvæ pass through a series of developmental changes, occupying about five days at average Colombo temperature, till they reach the stage when they become infective and are capable of penetrating the human skin.

During this period of growth, food granules are stored up in the body cells. These granules serve to nourish the mature larvæ till it reaches the trachea of its human host.

The immature larvæ are much less resistant to unfavourable conditions than the infective forms. Under the usual conditions obtaining in nature, only a comparatively small proportion of the larvæ hatched out of the eggs will reach maturity.

The most favourable culture medium for hookworm larvæ appears to be vegetable humus or mould such as is produced by the decay of vegetation on the surface of the soil. In addition to this kind of substance, air, enough, but not too much, moisture, and a suitable temperature are required. The presence of acid or certain salts is detrimental to the larvæ.

The dark gravelly loam at Narahenpita contains the high figure of 6·7 per cent. of humus, but is distinctly acid in reaction Ph. 5. 4. In other respects it seems well suited to the development of hookworm larvæ. Rich yields of infected larvæ have repeatedly been obtained by mixing infected human fæces with both Narahenpita earth and mixture of equal parts of sand and dried sludge from the septic tanks. As will be seen later, these larvæ survived for an exceptionally long period. They must therefore have been exceptionally well nourished.

The yield of larvæ obtainable from soil cultures varies greatly with the nature of the soil. Stoll reports 2·4 per cent. larvæ hatched from ova in Porto Rico clay and 66·7 per cent. larvæ from humus in the same locality. Sandy and sandy loam soils are intermediate.

Colombo can be divided roughly into areas where the soil is of cabook and other areas where it is principally composed of sand.

Bare cabook is somewhat deficient in the type of organic matter required for the development of hookworm larvæ. Once development took place, as it might on a surface layer of vegetable mould, the larvæ could survive long periods in moist cabook. Their movement, however, would be restricted to within a few inches of the surface.

Sandy regions are especially liable to hookworm infestation; especially where the sand overlies an impermeable stratum so that the ground water level is high.

If the surface of such a soil were well mixed with garden earth or humus, the conditions would become almost ideal for the development and survival of hookworm larvæ.

Larval Activities.—The movements and general activities of the mature infective hookworm larvæ are very characteristic and remarkable.

Placed in water in a shallow cell, the active larvæ exhibit frequent lashing movements, eventually finding their way to the margins of the cell where they remain head outwards in a continual state of agitation.

Movement increases with rise of temperature to blood heat. At lower temperatures movements may not be continuous, larvæ sometimes passing into a resting stage during which there is practically no expenditure of energy.

Larvæ in soil are found in the moisture film covering the soil particles. Their action is exerted between the resistance of the particle and the surface tension of the moisture film.

After travelling some distance through soil larvæ became noticeably more transparent, due to loss of their food granules, which when numerous render them opaque. The smaller the size of the soil particles, the greater the surface tension of their moisture film, the greater the resistance to larval movement and the more rapid the exhaustion of the larval store of energy, which cannot be replenished from without.

Observations made in the laboratory indicate that in a soil such as cabook, permeable to water, but resistant to larval motion, larvæ will remain more or less stationary for long periods if water is regularly added.

Till recently the idea prevailed that hookworm larvæ had great powers of lateral diffusion from an infected focus. This is certainly not the case. The slight lateral migration detected in Colombo soil was easily accounted for by the mechanical action of the currents set up after addition of water to the soil. Observations in the West Indies lead to a similar conclusion.

If the moisture content of the zone surrounding the infected fæces be artificially increased on a horizontal plane lateral migration will take place, but such conditions can seldom occur in the field.

Till recently many sanitarians considered that hookworm fæces could safely be buried under a shallow layer of earth without risk of the larvæ developing and ascending to the surface. Recent research shows that burial affords no such security, unless the soil is restrictive of larval movement.

Colonial Medical Reports.—No. 175.—Colombo (*con nued*).

Hookworm larvæ move upwards or downwards, according to the amount of moisture present in the different levels of the ground; if the ground surface is drying they descend to moisture levels; if the upper layers of the soil are moist they ascend till they reach the surface.

The extent of the vertical movements of hookworm larvæ appears to be governed principally by three factors:

(1) The size of the soil particles.

(2) The distribution of the ground water.

(3) The amount of energy stored up as food granules in the body of the larvæ.

Mature larvæ are usually provided with a sheath, which protects them to some extent from adverse influences. After moving even a short distance through compact cabook the sheath is lost.

Loss of sheath is much less marked after passing through a light sandy soil of the Narahenpita type. Only 20 per cent. of the larvæ added to cabook can be recovered by Baermann's method, whereas more than 80 per cent. can be isolated from Narahenpita soil.

Preliminary experiments were made in January and February, 1923, on the vertical powers of ascent of hookworm larvæ. Stools heavily infected with hookworm larvæ and the filariform larvæ of *Strongyloides stercoralis*, after mixing with earth, were buried at the bottom of pits dug in hard cabook near the laboratory to the depths of 6, 12, 18, and 36 inches. The shallower pits were filled with coarse river sand, Narahenpita soil, and loose cabook. Both species of larvæ ascended six inches through all three soils, and hookworm larvæ twelve inches through each soil, and through eighteen and thirty inches through sand.

It was proposed to repeat these experiments with definite quantities of larvæ, but in the meantime Florence Payne in America has published a report of such experiments in which numerous larvæ were recovered after an ascent of thirty-six inches through sand. She found in her experiments that the larvæ were unable to penetrate white clay, but ascended ten inches through a red clay.

The behaviour of hookworm larvæ in the surface of soil is of particular interest. Van Durme in 1902 drew attention to the remarkable attitude taken up by the filariform larvæ of *S. stercoralis* on the surface of particles of soil. Subsequently, it was found by other observers that both human and canine larvæ behave in a similar manner.

Larvæ attach themselves by one end to a particle of soil, preferably of fibrous nature, and extend themselves into the air. According to the writer's observations the motion of hookworm larvæ in this position is a slow to and fro wave movement as if continually reaching for a new support. The *S. stercoralis* larvæ exhibit a rapid jerky motion.

Florence Payne reports that larvæ do not expend much energy in maintaining this position, judging by the rate of disappearance of their food granules.

The larvæ may be observed to move from particle to particle on the surface by a species of looping motion. The aerial position is kept up for periods varying from a few minutes to half an hour or so at a time. Larvæ commonly cling together in aerial clusters which are readily visible to the naked eye on the surface of the soil. The surface of cultures of canine hookworm ova may be covered with waving plumes of larvæ.

The significance of this phenomenon seems clear. Perched in a favourable position on the surface of the soil the larvæ await their opportunity to come in contact with the human skin.

So far as known to the writer only infective nematode larvæ of the penetrative type behave in this manner. The free-living soil nematodes, though often very active in their movements, remain in the interstices of the soil.

Immediately contact is made with the skin a new set of forces comes into play leading to the penetration of the epidermis, the passage of the larvæ to the lungs, hence to the bronchi, trachea and œsophagus. Full development takes place in the intestines, if the host is adapted to the species of worm. *N. americanus*, the Ceylon species of hookworm, has only two hosts, man and the gorilla. The series of forces which brings the larvæ on to the surface of ground moistened by rain, thence to the summit of the soil particles, or as high up as leaves and twigs or the moisture film extends, thence into the skin, are analogous to the forces causing a plant to bend towards the light, or which drive a spermatozoon to its destination, the unfertilized ovum.

Pintner named the force thigmotropism, which causes the larvæ to penetrate small pores. Brumpt has called the driving force larvæ into tissues histotropism. Khalil has recently described under the name of thermotropism the tendency of hookworm larvæ to move towards a heated point. The tendency of larvæ to extend themselves into the atmosphere may be called aerotropism.

It is sometimes difficult to separate hookworm larvæ present in soil from the free-living forms having a somewhat similar appearance.

If a greater variety of larvæ are recovered from a mass of soil the task of scrutinizing them all under the microscope in order to make an accurate count of the hookworm larvæ is often excessively laborious.

Progress in hookworm research work has been mainly a question of development in technique. It was Baermann's discovery in 1917 of a convenient and reasonably quantitative method for isolating nematode larvæ from soil, which gave the impetus to modern research into the epidemiology of hookworm disease.

The writer has sought to facilitate the task of separating hookworm larvæ from free-living forms by taking advantage of the tropic reactions described above. It was found that hookworm larvæ will penetrate porous membranes such as filter paper, chamois leather, or buckskin with great ease. Non-porous leathers, parchment, rubber and similar substances are not penetrated. Larvæ penetrate into a membrane made of freshly dissected skin, but seldom pass through it.

The next step was to bring a membrane retaining a suitable fluid at blood temperature in an inverted tube or vessel lightly into contact with the surface of soil containing larvæ. The aerially extended larvæ then pass upwards through the membrane into the fluid, where they may readily be recovered free from soil particles and almost free from non-infective larvæ. The results are somewhat affected by the temperature of the atmosphere. It may be necessary to cool the under side of the receptacle containing the soil. A buckskin membrane was commonly used in these experiments.

A curious phenomenon was noted during these investigations (September, 1922, to January, 1923). If a pan of soil showing numerous aerially extended larvæ be placed in the incubator at 37° C. all the larvæ disappear from the surface of the soil. They re-appear in a few minutes at room temperature on the laboratory bench.

The technique can be adopted to any quantity of soil.

A second test found of value is that of applying the suspected larvæ to the skin of a rat. If the suspected larvæ are able to reach the lung of the rat within three days with production of hæmorrhagic congestion of the organ the result of the test is considered to be positive. Both canine and human hookworm larvæ give positive results to this test, provided sufficient numbers of larvæ are applied to the skin. Penetrative nematode larvæ of other species should doubtless give similar results. Free-living larvæ give negative results.

Tests of this kind cannot entirely replace the crucial experiment of applying the larvæ to the human skin and expelling any hookworms developed but enable such troublesome experiments to be reduced to a minimum.

Larval Life.—The viability of the infected hookworm larvæ is clearly a matter of great epidemiological importance and has accordingly been studied by numerous observers in various parts of the world.

Most of the workers in temperate climates were able to keep the larvæ alive for upwards of a year. Baermann in Sumatra observed living larvæ up to six months in a shady soil.

A series of reports, however, has recently been issued by the team of American observers working under the direction of W. W. Cort, placing the extreme length of survival of hookworm larvæ in the tropics at six to eight weeks. The experiments were carried out in Trinidad. The number of larvæ present in the soil diminished rapidly, both in the field under natural conditions and in laboratory experiments.

This conclusion, if correct, would justify a more optimistic view of our prospects of controlling the spread of the disease. The risk of infection from walking barefoot over such sites as that at Narahenpita or of handling sludge at Madampitiya would become negligible in a few weeks.

Before describing the results of the series of observations made in the laboratory, the principal factors governing the length of life of hookworm larvæ in soil may be briefly considered.

Stress has already been laid on the effect of rich culture media in supplying the larvæ with a good store of food granules during their development from the egg to the infective stage. Larvæ grown under poor conditions cannot be expected to live long. A constant supply of moisture is essential to long larval life. Much depends on the temperature; comparative observations made in this laboratory at room temperature 80° F. and in the incubator show that larval die out twice as rapidly at blood heat both in soil and in liquids. This is due to the increased larval activity produced by rise of temperature and the more rapid exhaustion of their food reserve. The constitution of the soil is of importance; in fine soils much more energy is wasted in reaching the surface. Acid soils and soils containing excess of salt are most unfavourable to the larvæ.

Similar results, therefore, can only be expected under similar conditions.

Observations were made on the length of life of hookworm larvæ both in the field at Narahenpita and in the laboratory in various soils contained in pots and jars, and in a trench in the laboratory grounds.

The Narahenpita trenching ground was divided into blocks and each block into numbered trenches. To prevent waterlogging the trenches were covered with ridges of earth. Abundant crops of grass are raised on the site and sold as cattle food. The whole area was trenched over in about eighteen months. As accurate records were kept of the numbers of the trenches dug each day in any block the number of days since night-soil was buried in any particular trench was definitely known.

The observations, begun in 1920, were brought to a conclusion some months after the closing of the depot on June 27, 1922.

Larvæ apparently identical with hookworm larvæ could be recovered in small numbers from the soil of trenches up to 113 days old.

A report by Mhaskar has just appeared on the survival of hookworm larvæ in a similar trenching ground at Trichinopoly, India

Larvæ were recovered up to fourteen weeks (ninety-eight days).

On December 21, 1922, heavily infected human fæces were buried in an eighteen-inch trench dug in the cabook behind the animal house at Maligakanda. The trench was watered daily. The day before the writer left the island for Europe a few larvæ were still present in the soil of the trench, i.e., eighty-eight days after the commencement of the experiment.

Conditions in the field are variable, particularly as regards rainfall. A rapid increase of larval mortality may be produced by a spell of dry weather or some other temporarily unfavourable factor.

What the sanitarian needs to know are the maximum length of survival and some idea of the rate of mortality under the most favourable conditions likely to be met with in his locality. To throw light upon this problem a series of

laboratory experiments were carried out, in which an attempt was made to eliminate the influence of unfavourable factors. The results of the more important experiments are summarized in the following schedule.

Number	Nature of soil	Kind of receptacle	Number of days larvæ survived	Rapid falling off in numbers after
1	Sand and sterilized sludge equal parts mixed with infected human fæces	Baking pan	124	68 days.
2	Sand and sterilized sludge equal parts mixed with infected human fæces	Baking pan	108	87 days.
3	Sterilized Narahenpita earth with hookworm stool	Baking pan	124	89 days.
4	Sterilized Narahenpita earth with hookworm stool	Baking pan	120	78 days.
5	Sterilized Narahenpita soil finely sieved	Pot	14	1 day.
6	Sand and unsterilized sludge	Pot	9	1 day.
7	Unsterilized cabook soil	Pot	120	69 days.

The two inches of earth in the pans was protected from flies by wire gauze, covered with a layer of wood ash and watered daily with a sufficient uniform amount of sterile distilled water to keep it slightly moist. The pans were perforated for drainage. The pots were ordinary flower pots of the cylindrical pattern. Larvæ cultivated from human fæces were placed in the upper three inches of the soil in the central axis of the pot. There was very little lateral and no downward migration.

Sterilized soils were only heated sufficiently to kill any nematode larvæ present and not enough to markedly affect their chemical composition.

The rapid disappearance of the larvæ in experiment No. 5 was undoubtedly due to the impermeability of the finely sieved soil to water. A solid crust formed on the surface. In its natural condition, full of coarse matter, root fibres, &c., this soil is readily permeable to water. The disappearance of larvæ in experiment No. 6 may be attributed to putrefactive changes in the soil. Swarms of protozoa were present which may have had a detrimental influence on the larvæ. Numbers of dead larvæ were recovered from the pots showing much the same degenerative appearance as larvæ kept in septic tanks for over three days. These two experiments serve to illustrate the operation of unfavourable factors on the survival of hookworm larvæ.

Some of the larvæ kept in tubes filled with Colombo tap water exhibited active movements of translation up to the ninety-eighth day. A few could still be stimulated to move a little after nine days.

The larvæ in all these experiments became more and more transparent with increasing age.

The results of the Trinidad experiments show a rapid larval mortality from the first few days of the experiment.

The larval numbers did not fall off rapidly in the course of four of the Colombo experiments till about the seventieth day.

On the basis of the writer's results six months would seem a fairly safe limit for the survival of hookworm larvæ under conditions likely to be met with in Colombo. During the hot dry weather the viability of the larvæ would be much less, whereas up country it would be probably much greater.

More information is required concerning the rate of re-infestation after treatment. This rate seems the best epidemiological guide to the sanitary state, qua hookworm, of any particular district. The rate depends not only on the degree of hookworm infestation of the soil itself, but also on the sanitary habits of the population group.

Baermann was disappoined to find that heavily infected coolies working in rubber and tobacco estates in Sumatra, after a thorough course of treatment for hookworm disease, became steadily re-infected till finally after one or two years they harboured an average of about 738 worms and consequently urgently required another course. The average number of worms acquired per day rose from ·75 to 1·3 per coolie. Latrines were used in these estates. Baermann traced the source of infection to patches of larvæ-infected soil in the neighbourhood of these coolies' dwellings. The larvæ were probably brought to the spot originally in particles of fæces adhering to the coolies' feet after a visit to dirty latrines. Each day the coolies had occasion to visit the infected spot and acquired additional infection.

As hookworm do not die out rapidly in the common Ceylon soils investigated there would be ample opportunity for the establishment of infective foci on the surface of the ground, especially in those districts unprovided with latrines.

The continued infectivity of these soil foci would depend upon the balance in between the rate of death of old, and the rate of development of new, larvæ in the same situation. A vicious cycle tending to continually increase human infestation would become established under particularly unfavourable conditions as regards soil infestation.

It is difficult to know what interpretation to place on the epidemiological data relating to the Madampitiya outbreak in 1919. The conclusion arrived at by several independent investigators, that hookworm larvæ must have survived in the soil at least two years is not likely to be accepted in the present state of our knowledge without absolutely convincing evidence.

The results of the writer's investigations do not exclude the possibility that hookworm eggs or larvæ may, under a specially favourable combination of circumstances, remain in a dormant or resting stage in the soil for extraordinarily long periods.

It is probable, however, that larvæ seldom survive for such exceptional periods under tropical conditions.

There are three principal measures for the control of hookworm infestation among a barefooted population.

(1) Periodic treatment campaigns.

(2) Provisions of sanitary latrines and education in their use.

(3) Paving or hard packing of the ground surface in the vicinity of dwellings.

The relative utility of the third measure increases

in proportion to the viability of larvæ in the soil covering the ground near human dwellings.

An infestation rate of 40 per cent. of the population is somewhat high for a well-latrined city such as Colombo and is probably to be accounted for by the suitability of much of the soil for the development and survival of hookworm larvæ.

Though there is little actual hookworm disease due to the direct action of the parasites, yet this degree of infestation must have a considerable indirect effect in lowering the general vitality of the population and decreasing their powers of resistance to more serious diseases.

The steady increase which is taking place in the number of water carriage latrines and of hard paved surfaces near human dwellings should bring about a gradual decrease in hookworm infestation throughout the city and a corresponding improvement in the public health.

CONCLUSIONS IN REGARD TO CONTROL OF HOOKWORM DISEASE.

(1) The reconstruction of the septic tanks at the sewage works has not only improved the effluent chemically and physically, but diminished the risk of hookworm larvæ passing out with the effluent or sludge.

(2) The sludge from the septic tanks may be safely sold as manure after being thoroughly sun-dried and kept in dry store for six months.

(3) The site of the Narahenpita trenching ground is now free from hookworm infestation derived from buried night-soil.

(4) The labour force employed in clearing the sumps and sewers are exposed to grave risk of contracting hookworm disease. The sumps of pumping stations should be emptied as far as practicable by mechanical means. Coolies should not enter the sumps or sewers without adequate protection for their feet and hands.

(5) Hookworm larvæ are capable of ascending a considerable distance through loose soils. Hookworm infected fæces cannot be buried in such soil without risk of infecting the surface of the ground.

(6) Hookworm larvæ cultured in soils rich in organic matter can survive at least four months in typical Colombo soils.

Colonial Medical Reports.—No. 176.—Seychelles.

ANNUAL REPORT ON THE MEDICAL DEPARTMENT OF SEYCHELLES FOR THE YEAR 1923.

PUBLIC HEALTH.

Vital Statistics.

THE estimated population of the colony on December 31 was 25,700, and the birth-rate was 30·62 per 1,000 and the death-rate 11·79 per 1,000.

There were no infectious or contagious diseases treated during the year.

The excellent work carried out by the Rockefeller Institution in combating the hookworm infection should not be allowed to lapse. Over 80 per cent. of the population is heavily infected; with the increase of staff in 1924, as far as local means will permit the campaign will be continued. The same remark applies to leprosy, when the campaign will be commenced on modern lines as soon as the necessary injections arrive from England. Compared with other tropical places the colony compares favourably, the death-rate is low, there is no malaria, at times sporadic chicken-pox occurs, and with the exception of leprosy, amœbic dysentery and an odd case of beriberi from the outlying islands most tropical diseases are unknown.

Syphilis is prevalent and gonorrhœa is common, and these two diseases, coupled with ankylostomiasis, are responsible for most of the ills of the community. The usual parasites of the nematoda, such as *Ascaris*, *Trichocephalus dispar*, *Filaria*, *Strongylus* and *Oxyuris* are quite common.

Leper Camp, Round Island.

Formerly the Leper Camp was situated on a little island close to Praslin, but three years ago it was removed to Round Island, situated in Victoria Harbour, about two miles from the mainland. The lepers are each provided with a wooden hut, and they are better housed and fed than people of their condition in civil life. There are at present fourteen lepers in the camp, all males, each provided with his own small house, there is a guardian in charge and a dresser is also attached to the camp. The supply of rations is good, and a medical officer visits the camp at least once a week, oftener if necessary.

Lepers are prohibited from taking part in occupations that would directly or indirectly bring them into contact with food or drink intended for others. The main Ordinance gives power to segregate pauper lepers and lepers of well-to-do families on a responsible person signing an agreement to look after them and see that they carry out the restrictions laid down by law. We have twenty-five lepers segregated and looked after by their next-of-kin, they are visited from time to time by the Sanitary Officers and if they do not comply with the regulations there is power to intern them in the leper camp.

The upkeep of the leper camp for 1923 was Rs. 3,397.95.

Colonial Medical Reports.—No. 177.—Sierra Leone.

ANNUAL MEDICAL AND SANITARY REPORT FOR SIERRA LEONE FOR THE YEAR 1923.

General Remarks.

Freetown was free from epidemics of any sort; outbreaks of yellow fever were reported from several ports on the Gold Coast and plague was reported from some of the neighbouring French and Spanish possessions, necessitating the enforcement of quarantine regulations for short periods; no case of either of these diseases occurred in the colony.

The Cape Quarantine Station was requisitioned once during the period for contacts (some sixty in number) from a German boat, on which was found a case of confluent small-pox; there were no other cases.

There were sixteen cases of chicken-pox and two cases of small-pox treated at the contagious diseases buildings at Kissy flats.

General Diseases.—Rare; the following were observed: pernicious anæmia, one; exophthalmic goitre, two; rickets, three; lymphadenoma, two; gout, one.

Rheumatism.—Acute rheumatism and rheumatic fever are not common; chronic rheumatism—articular and myalgic is fairly widespread.

Dysentery.—There was an increase of fifty-four in the number of this disease treated in 1923.

Tuberculosis.—This for the last four years shows a steady and somewhat alarming increase; the increase is more evident amongst the Creole population, which is not surprising in Freetown, when one realizes the overcrowding of houses, want of air space and ventilation, and the apparent overcrowding in the houses themselves.

Venereal Diseases.—Gonorrhœa and syphilis show a steady increase in the numbers treated.

The figures in these diseases are only the cases treated by Government medical officers, and one fears they are not all representative of the true numbers. Whether the disease be gonorrhœa or syphilis, the native, through indifferent or persistent negligence, fails to come for treatment until almost incapacitated; in the meantime he may be spreading the disease far and wide.

Communicable Diseases.

Insect Borne. Yellow Fever.—There was no case during the year. Yellow fever restrictions were observed for a short time owing to the suspicious illness of a European in the nursing home; however, the post-mortem cleared all doubts and all restrictions were removed; during the time of restrictions a very useful lot of fumigation and intensive anti-stegomyia work was effected.

Trypanosomiasis.—One case was discovered in a child while attending out-patients; she was removed to hospital, but before treatment could be completed she was taken away by her parents against the advice of the medical officer in charge and lost sight of; she was supposed to be a native of Sherbro.

Malaria.—This disease is widespread, both in the Colony and Protectorate. It is, however, gratifying to note a decrease of 1,609 malarias and three blackwaters during the year; the good effects of the anti-malarial measures, taken wherever the sanitary department is, are bearing fruit in no uncertain manner.

Infectious and Epidemic Diseases.

Small-pox—Freetown.—One imported case, one non-imported case. Protectorate—some seventeen cases were reported from various parts of the Protectorate; no deaths were notified.

Chicken-pox.—This disease was reported fairly frequently both in Freetown and the Protectorate; sixteen cases were isolated at Kissy.

Measles.—This disease was common in the colony and Dr. Taylor reported on an outbreak in the Port Lokko district, where there were eighty cases, with six deaths.

Beriberi.—Including the forty-three cases at the prison fifty-five cases were treated.

Fuller details of these diseases are given in the sanitary section.

Helminthic Diseases— Ankylostomiasis.— This disease is widespread; each medical officer submits an annual special report on this disease. All these diagnoses are based on microscopical examinations. Treatment by carbon tetrachloride, thymol or beta-naphthol or oil of eucalyptus gave satisfactory results.

Ascaris was found in 1,296 of the cases examined and *Tænia solium* or *T. saginata* in 146 cases.

Preventive Measures against Insect-borne Diseases.

The following is taken from the report of Dr. J. M. Mackay, M.C., Acting Medical Officer of Health, Freetown:

House to House Inspection.—98,002 inspections of houses and compounds were carried out during the year, 578 mosquito breeding places being found.

Mosquito Breeding Places.—The total number of mosquito breeding places discovered and dealt with was 1,121.

Closing of Wells.—At the end of 1922 there remained, so far as was known, only two wells to be closed. These were closed during 1923 in addition to four others, whose presence had not previously been detected. Practically all wells have now been closed.

Cesspools.—The usual disinfecting during the dry season and oiling during the rains was carried out.

Canalization of Streams.—Towards the end of the year, Alligator, Sanders and Nicol's Brook were regulated and canalized, all mosquito breeding pools, &c., being filled in.

Filling in of Low-lying Land.—A considerable area of low-lying land in the vicinity of the new concrete drain in Sanders Street was raised and drained, thereby obliterating a great number of potential mosquito breeding places.

Oiling of Pools and Gutters.—40,122 pools and gutters were oiled by inspectors in charge of sections and 26,035 by the oiling gang which operated for six months.

Inspection of Trees.—During the latter half of the year, a systematic inspection of trees was carried out. 25,046 trees were inspected and 5,352 holes, likely to contain water in which mosquitoes might breed, were found. 2,900 of these holes were cut so as to prevent water lodging there and 2,452 holes were cemented. 111 mosquito breeding places were found.

Yellow Fever.

The death of one European in Freetown, which occurred in September, was attributed on clinical grounds to yellow fever, but pathological examination showed that death was due to a streptococcal septicæmia.

Trypanosomiasis.

Trypanosomes of the *gambiense* type were found in the blood of a child who was brought to the Cline Town dispensary. Unfortunately, the patient disappeared after the diagnosis was made, and all efforts to trace her were unsuccessful.

The Registrar at York, who is a dispenser, recorded one death in an outlying village as probably due to trypanosomiasis, but he did not see the case and the diagnosis was based on a description of symptoms given by the relatives.

In accordance with recommendations made by Prof. Blacklock in a report published in the last annual Medical and Sanitary Report (Appendix viii), fifty prisoners were sent to the Cape Sanitary Station early in October and for the remainder of the year they were employed in clearing the Cape Peninsula with a view to getting rid of the tse-tse fly. On former occasions it had been assumed that the oil-palms on the Cape Peninsula were of economic value and the method of treatment adopted was merely to remove the lower petioles in order to deprive the fly of breeding shelter. It is now realized that owing to extensive tapping for the purpose of obtaining palm-wine the trees have become valueless, except from the æsthetic point of view. It was therefore decided to cut down all trees low enough to provide shelter for the fly and leave only the tall ones. By the end of the year this had been done on about half the peninsula and, if certain difficulties with regard to privately-owned land can be overcome, it will be continued until the whole of the peninsula has been cleared. Efwatakala grass was grown from seed in the compound of the sanitary station and this will be planted out at the beginning of the next wet season.

Relapsing Fever.

In consequence of reports of this disease from the Gold Coast and of its recent extension in a severe form over a large area of French West Africa, medical officers in this colony were warned to be on the look-out for it. Dr. Maplestone, assistant director of the Sir Alfred Lewis Jones Research Laboratory, Freetown, kindly examined a series of blood-films taken from cases of fever in various parts of the colony and protectorate. All of these were negative for spirochætes, and Dr. Maplestone stated that he considered it "unlikely that relapsing fever is at present endemic in this colony."

Preventive Measures against Infectious and Epidemic Diseases.

Cerebrospinal Meningitis.

A solitary case at Pujehun, which was considered by the medical officer to be cerebrospinal meningitis, was notified in August. The cerebrospinal fluid was purulent and showed microscopically "numerous masses of degenerated leucocytes with diplococci in pairs and short chains of pairs intra- and extra-cellular." Death occurred on the tenth day and there was no post-mortem.

Plague.

In Freetown, 13,168 rats were brought to the department during the year and were destroyed. They were paid for at the rate of 2d. each until September, when the rate was reduced to 1d. During the year Dr. Maplestone, of the Sir Alfred Lewis Jones Research Laboratory, carried out a series of examinations of rats for *B. pestis.* No infected rats were found. The department continued to use rat-catching varnish, which proved as before to be highly satisfactory. There is a sufficiently large percentage of *X. cheopis* present on rats in Freetown to carry plague effectually in epidemic form, should this disease be imported. The great difficulty is of reducing the rat population owing to the vast amount of natural shelter. Modern experience indicates that the only satisfactory method of getting rid of rats is to build them out, and this is a point worthy of serious consideration when building regulations are drafted. A town-planning scheme with a view to getting rid by degrees of the congested areas of Freetown would do much to reduce the danger of plague which, under existing conditions, is an ever-present one.

Small-pox, Chicken-pox, Vaccination.

In Freetown two cases of small-pox were notified during the year. One was a non-imported case on the western outskirts of the town, but the source of infection could not be traced. The other case was landed from the German S.S. "Tsad." Seventeen cases were reported from the protectorate, nine of

these from the Koinadugu district of the northern province and the remainder from the southern province. Chicken-pox was reported fairly frequently both in the colony and protectorate. There was an outbreak, consisting of seventeen cases, at the Agricultural Training College at Njala, the source of infection being a boy who came from a town in the southern province, where chicken-pox was prevalent.

Dysentery.

It is difficult to give accurate figures with regard to the incidence of dysentery. At the Colonial Hospital, Freetown, 138 cases were treated in 1923. Now that the wells in Freetown have been closed it is unlikely that this disease is to any extent waterborne and, as flies are seldom numerous, it is improbable that they have much to do with it. Its continued prevalence is probably to be attributed to "carriers" and to insanitary conditions of living, especially as regards the handling and storage of food.

Leprosy.

Three new cases were treated at the Kissy Infirmary. Others reported were three in Freetown Prison, four at Daru and three at Bonthe.

It is hoped that when the natives begin to realize that the new methods of treatment hold out promise of cure they will bring their cases more readily to the various dispensaries, as has already happened in India, and that in time real progress will be made in the eradication of this disease.

Tuberculosis.

There is reason to believe that tuberculosis, especially the pulmonary form, is very prevalent in Freetown and that it is increasing. Eighty-three cases were treated at the Colonial Hospital in 1923. The African has none of the resistance, inherited or acquired, to this disease that the European possesses, and he is liable to fall an easy prey to it. There can be little doubt that congested areas and overcrowded and insanitary dwellings have a great deal to do with the prevalence of this disease in Freetown. It is probable that ankylostomiasis and other helminthic infections are important predisposing causes. The risk of infection through meat or milk is almost entirely absent and we have to deal no doubt with the human strain, transmitted by close and direct contact in small ill-ventilated rooms.

Anthrax.

Dr. J. M. Mackay, M.C., Acting Medical Officer of Health, Freetown, reports as follows: "During the year three cases of anthrax amongst cattle were discovered. The first case was found on January 16, a cow which had died on that day. The second case occurred on February 5, also a cow which died on that day. The third and last case was found on December 10. This was a bullock which, on inspection before slaughter, appeared to be quite healthy. After slaughter the condition of the spleen was suspicious, and on bacteriological examination *Bacillus anthracis* was demonstrated. One sheep also died of anthrax on March 12. No case of human anthrax was discovered." At Bo two bullocks suffering from anthrax were destroyed.

Diphtheria.

Two cases of diphtheria, treated at the Princess Christian Mission Hospital, were notified by Captain Wade, R.A.M.C. As far as can be ascertained these are the first cases recorded in this colony.

Other Diseases.

Measles was prevalent during the second quarter of the year in the colony and it was also reported from the Port Lokko district of the protectorate. Eighty-five cases were treated at the Colonial Hospital, eighteen at Kissy, twenty-eight at Songo and forty-eight at the Port Lokko dispensary. As a rule the type was mild, but in an outbreak at Magbankitta, in the Port Lokko district, there were nine cases with six deaths.

Whooping-cough was also prevalent in the colony during the second quarter; 109 cases were treated at the Colonial Hospital, Freetown, seventy-five at Bonthe and thirteen at Waterloo.

PORT SANITARY WORK, FREETOWN.

The Port of Freetown was never in quarantine during the year. All ships arriving from infected places were visited and inspected by the Medical Officer of Health. One case of small-pox was discovered on the S.S. "Tsad" in July and the usual precautions taken, viz., disinfection of the ship, vaccination of contacts and the isolation at the Cape Sanitary Station of all persons landing in Freetown.

A case of scarlet fever was landed from S.S. "Boutry" in February and treated at the Kissy Infectious Diseases Hospital. This steamer was homeward bound after a stay of some weeks at various West African ports and the source of infection could not be determined.

VITAL STATISTICS.

The death-rate of 30 per thousand in Freetown compares with a rate of 26·3 in 1922, the actual number of deaths being 1,332 in 1923, an increase of 171. In view of the fact that only 17 per cent. of the deaths were certified by a medical practitioner, it is difficult to state the exact reasons for this, but it is worthy of note that there was an increase of 106 in the deaths under three years. With the exception of measles and whooping-cough, in the second quarter, there was no outbreak of infectious disease during the year. A study of the deaths month by month shows that the increase was spread over practically the whole of the year and was most marked in the months of April, July, August, October and November. Generally speaking, the highest death-rate occurs during the wet months of the year.

NURSING HOME AND COLONIAL HOSPITAL.

Blood.—Eight hundred and thirty-one samples examined chiefly for suspected malaria. *Plasmodium falciparum* was found on 207 occasions, *P. vivax* on four and *P. malariæ* on four occasions also. The results emphasize the fact that the vast majority of cases of malaria in Freetown are of the so-called malignant type.

It is a very exceptional occurrence to find the sexual forms of this parasite in the peripheral blood of the patient. In one case only during the year were they observed.

As the presence of these cells is necessary for the transmission of malaria from one case to another, it will be of interest to find if they are more common in nocturnal blood.

Ninety-two specimens of sputum were examined, in fourteen of which *Bacillus tuberculosis* was found.

Twenty-three specimens of pus, chiefly from cases of suspected venereal disease, were examined. One specimen taken from the nose was found to contain *B. lepræ*. Four hundred and two specimens of fæces were examined, in which were found ova of *Ankylostoma*, *Ascaris lumbricoides*, *Trichuris trichiura*, *Tæniidæ* and *Entamœba histolytica*, either in cyst or as free forms.

The comparatively low percentage of cases harbouring ankylostome ova is explained by the fact that the majority of patients from whom these results are obtained are accustomed to wearing boots or shoes and so one of the chief roots of infection (i.e., through the skin of the feet and ankles) is closed. The percentage of patients harbouring ankylostome ova in the Freetown Prison is considerably higher.

REPORT ON ANKYLOSTOMIASIS, BERIBERI, AMŒBIASIS, LEPROSY AND BILHARZIASIS IN FREETOWN PRISON.

Ankylostomiasis.

The prisoners found infected were treated by different methods and the stools examined for adult worms. At the end of a week the fæces were again examined for signs of infection. Those found negative were re-examined weekly until three examinations had proved negative. Those found positive were given a second course of treatment and the same method of examination followed. One prisoner still found positive was given a third course and his fæces examined in the same way. Unfortunately, a large proportion of the prisoners (being short sentence men) were discharged before the full routine could be carried out, therefore the results are incomplete. All cases were under identical conditions, being admitted to the prison hospital during week-ends and kept in bed on low diet. No ill-effects were observed during or after any course of treatment.

Methods of Treatment.

A.—Beta-naphthol 40 gr. (in powder) followed in one hour by thymol 30 gr. and mist. alba 4 oz. after four hours. B.—Carbon tetrachloride 30 to 45 minims on bread. C.—Ol. eucalypti 30 minims, chloroform 40 minims, ol. ricini 10 dr., divided into two doses with one hour interval. D.—Ol. chenopodii 30 minims in milk.

No oil of chenopodium was in stock and a very small quantity only was obtained privately from Dr. J. E. Wright.

Conclusions.

Beta-naphthol.—Thymol is the most successful form of treatment, while eucalyptus is a failure, in dealing with ankylostome infection in Freetown Prison, but further work is necessary on account of the small numbers dealt with and the incompleteness of records owing to discharges.

Beriberi.

It is now possible to give details of the 1922 outbreak which lasted well into 1923. The total number of cases was 63. Of these, eighteen relapsed after being apparently cured; several relapsed twice and even thrice.

Number of deaths, three; number released on medical grounds, five; average stay in hospital, nine weeks.

Treatment.

Various combinations of tinct. ferr. perchlor, ferr. et ammon. cit., tinct. digitalis, liq. strychninæ, acid. phos. dil.

The most successful in the wet type of case was R: Mist. diuretica 1 oz. (pot. acet., spt. juniper, hyosc., and scoparii). Tinct. digital. 5 minims to 10 minims, tinct. nux. vom. 5 minims, aq. ad. 2 oz., t.i.d.

Amyl nitrite.—Inhalations were found of great benefit in tiding bad cases over thoracic crises.

Dry yeast, moistened and made up into pills, was administered, dose from ½ dr. twice daily.

Marmite.—1 dr. twice daily was used for one case with no marked beneficial results.

Diet.—Bread, 12 oz.; agidi, 1 lb.; beef, ½ lb.; sugar, 2 oz.; rice, 3 oz.; lard, ½ oz.; salt, ½ oz.; pepper, ¼ oz. For a time ½ lb. bread and ¼ lb. sweet potatoes were substituted for the rice without much benefit.

Extras—Barley water, milk, beef-tea, sweet potatoes, groundnuts, bananas, pawpaws, tomatoes and oranges.

In August, 1923, the four chronic cardiac and ataxic cases resulting from beriberi were released, thus bringing the outbreak to an end.

Amœbiasis.

An attempt was similarly made to deal with prisoners infected with amœbic cysts (*Entamœba histolytica*) i.e., those who were serving as carriers for potential amœbic dysentery. Owing to the discharge of short sentence men it was impossible to deal with all those found infected.

Method of Treatment.—One examination only of each was made. Those found positive were treated with:

A.—Tabella emetine c. bismuth. iod. administered thus: ½ gr. daily for two days, 1 gr. daily for four days—total 6 gr. Those found positive in a single examination one week after treatment received a second similar course.

Colonial Medical Reports.—No. 177.—Sierra Leone
(continued.)

B. Emetine hydrochloride administered hypodermically (in the case of weakly patients considered unfit for the more strenuous bismuth emetine iodide) thus: ½ gr. daily for two days, 1 gr. daily for four days—total 5 gr., followed where necessary by a second course of treatment.

Leprosy.

A more detailed account may be given of the two cases of leprosy treated during the first six months than could be done in the quarterly reports.

Case A.—Tribe—Temne—undergoing a life sentence—had been isolated on admission two years ago with a diagnosis of leprosy. He was considerably mutilated by the disease, and was unable to rise from the ground. He could barely crawl and had to be carried in the arms. Sensation was entirely lost, so much so that after two months' treatment, when a hypodermic needle was accidentally broken off in a vein, an incision was made, the vein picked up and the needle extracted without his being aware of anything having happened. His veins were at all times difficult to find, appearing and disappearing in different parts of his limbs.

Treatment.—Ol. chaulmoograe 750, chloroform 250, acid carbolici 10.

Of a mixture in these proportions 5 minims gradually increased to a maximum dose of 20 minims was administered intravenously daily for six days in each week for five months. Injections were made into veins in arms, back of hands, legs, over arch of foot, &c., wherever one could be found. If no vein could be discovered the injection was given intramuscularly. In all he received 81 intravenous and 13 intramuscular injections. One intravenous and one intramuscular developed into abscesses. At the end of this course he was given ol. chaulmoograe 30 minims on bread daily up to the present date.

Results.—The first sign of improvement was noted after three months' treatment, when he was able to stand if supported. The following month he was able to walk a little with the assistance of a stick, but still staggered and frequently fell. Progress continued steadily till the end of the five months, when he was able to walk upright without support or aid, and to ascend or descend stairs. Sensation has now been fully regained and for some time he has been doing light manual labour.

Case B.—Tribe—Mende—undergoing a sentence of two and a half years' hard labour and now on the point of discharge, was also diagnosed and isolated prior to my taking over the prison. He was shown to the local branch of the British Medical Association as a typical case of anæsthetic leprosy, large pale or pink-edged areas of anæsthesia covering much of the body and limbs, into which pins could be thrust almost one-fourth of an inch without the patient perceiving it.

Treatment.—The same mixture and dose but entirely intravenous, the majority of the injections being made into the same spot in the same vein day after day. After five months' treatment of 124 injections he was placed on treatment by mouth.

Results.—The majority of the patches have disappeared while sensation has returned in full.

Bilharziasis.

Two prisoners were found to be suffering from urinary bilharziasis. Both were Mendes, one from Kennema, the other from Pendembu. They were treated with antimony tartrate intravenously, ½ gr. dissolved in 10 c.c. normal saline gradually increased to a maximum of 2 gr. every alternate day, until a total of 25 gr. had been administered. Treatment in one of the cases had unfortunately to be suspended for three weeks, when only half the total had been administered, owing to the development of an abscess, and was resumed later. Active eggs were still present in the urine on conclusion of his treatment. He was given a few weeks' rest and a full course was then again administered, with the result that his urine was still negative some months later, although repeatedly examined during that time. The other case was negative, and remained so for some months after one full course of treatment. Both are cured.

Rat-Fleas in Freetown, Sierra Leone.

Hirst's (1923) work has attracted attention to the importance which must be attached to the relative proportion of various species of *Xenopsylla* on rats in places which appear liable to plague epidemics. He concluded from his observations that *X. astia* was a much less efficient transmitter of plague than is *X. cheopis*.

In Freetown a hundred rats sent by the Sanitary Department were examined during the months of January and February, 1923. The rats came from various parts of the town; the numbers were: black rats 62, brown rats 38. All the fleas removed from the rats were collected, a total number of 657. Of these, 654 belonged to the genus *Xenopsylla* and three to the genus *Ctenocephalus*. The 654 *Xenopsylla* comprised 419 fleas of the species *X. braziliensis* Baker (1904), and 235 of *X. cheopis* Rothschild (1903). The *Ctenocephalus* belonged to the species of *C. canis* Duges.

No *X. astia* were found on these rats; Evans (1922), however, records it among rat-fleas sent to her from the Gold Coast.

Xenopsylla braziliensis Baker (1904), was originally described from Sierra Leone, but its capacity for transmitting plague bacilli has not so far been worked out. Whether it exhibits that relative inability which Hirst attributes to *X. astia* in Ceylon is unknown.

It is of interest to note that Newstead and Evans (1921), who examined 469 black rats from ships in Liverpool (59 of these rats being obtained from ships coming from various West African ports) do not record any *X. brasiliensis* from 469 rats examined, whereas they found 489 *X. cheopis*. Again, Balfour (1922) did not report any *X. brasiliensis* on 34 black and 444 brown rats obtained mostly in

London, whereas he reports *X. cheopis* on 5·9 per cent. of the black rats and 3·6 per cent. of the brown rats. Hirst (1923) states that *X. brasiliensis* is found on the rats of West Africa, South America and the uplands of Peninsular India.

Cragg (1920) states that *X. braziliensis* is not common in India and cites Poona, Mangalore, Bombay City and Ootacamond as the only places from which it had then been recovered by him.

Owing to the smallness of the numbers of West African ship rats examined here and in Liverpool it is not yet possible to say whether *X. brasiliensis* is capable of remaining alive during transport on ships to England.

Whether *X. braziliensis* is a plague-transmitting flea or not, it appears from our figures that there is a sufficiently large percentage of *X. cheopis* present on rats in Freetown to carry plague effectually in epidemic form should this disease be imported.

The number of rats in Freetown is large, and owing to the extensive area which is at present capable of providing natural shelter for them, it is evident that vast numbers would survive any ordinary efforts at reduction.

The city of Freetown possesses many quarters in which the native population is overcrowded, and it also contains a large floating population. All these factors are of importance in the case of plague epidemics. The chief protection of this port from the introduction of plague from other coastal regions in the past is probably the absence of a deep water wharf.

Report on an Investigation into the Prevalence of Goitre in the Protectorate of Sierra Leone.

Introduction.

This investigation into the prevalence of goitre in certain districts in the Protectorate of Sierra Leone was undertaken during the months of December, 1923, and January and February, 1924. The districts traversed were the mountainous Konno and Koinadugu districts, but parts of certain tribal areas outside the limits of those districts, e.g., part of the Mende country, part of the Limba country, and part of the Temne country also came under review.

Past and present theories about Goitre.—Before entering on a detailed statement of the conditions found in Sierra Leone, it is convenient to analyse first the various theories and suggestions which have been advanced as to the causation of goitre, and then later to show in what respects the facts in Sierra Leone conform to such theories. The influence of heredity, sepsis and other factors will be mentioned later.

Geographical Theory.—Formerly endemic goitre was considered to be mainly a geographical and geological disease; it was held that it occurred only in countries situated far from the sea at a high altitude, and in certain geological formations. The influence of meteorological conditions was considered important and of such rainfall, damp, and absence of sunshine in valley situations were most frequently emphasized.

Deficiency and Excess Theories.—Arising in part out of the geographical theory, and connected with it, are certain theories which have been current for many years and which attribute the enlargement of the thyroid gland to the absence from or excess in food or water of certain constituents which are essential to the normal functioning of the thyroid gland. In Gippsland, Australia, insufficiency of lime in the food or water has been considered to be the chief factor in producing mild goitrous symptoms; the success of treatment there by the administration of calcium salts seemed to bear out the correctness of this theory. On the other hand, in Derbyshire and Switzerland thyroid enlargement and enlargement of the parathyroids have been attributed to excess of calcium salts.

In the year 1896 Baumann, of Freiburg, discovered in the normal thyroid gland an iodine-containing substance, to which he gave the name thyro-iodin. This finding had a definite bearing on a theory then already held by some in Switzerland that it was a deficiency of iodine which was the cause of thyroid hypertrophy. It was now proved that the thyroid gland of goitrous persons differed in chemical constitution from that of normal persons by being deficient in iodine. This discovery appeared to confirm the idea that the thyroid gland of goitrous persons is deficient in iodine, because of a natural deficiency of iodine in the food and water ingested.

The Infective Theory.—For a period the idea that goitre arose as the result of infection by micro-organisms gained ground. McCarrison (1913 to 1914) stated "I have adduced evidence to show that the causal agent of the disease (endemic goitre) is a micro-organism which, having its habitat in the soil of endemic localities, gains access to the bodies of men and animals by means of water, soil-contaminated food, soil-contaminated hands or other means, and living in the alimentary tract of the infected individual gives rise to those toxic products which, on absorption to the blood-stream, stimulate the thyroid mechanism to increased activity. In a certain portion of all cases this increased activity results in the development of visible goitres, and is the starting point of those many degenerative processes which ultimately involve the hypertrophied organ." The idea of a living organism being *directly* responsible for the enlargement by infection of the thyroid itself or by general infection of the blood, was negatived by certain experiments conducted by the same author; he proved by cultural methods that fœtal goitre in goats did not yield living micro-organisms. From this date onwards the micro-organismal nature of the disease has been studied carefully; the less recent developments of the micro-organism theory were rather in the direction of showing that the organism exists not in soil but in fæces of goitrous men and animals, and is capable of producing goitre in healthy animals which are fed on such fæces or on cultures prepared from such fæces. The suggestion here, as before,

is that the organism, having reached the alimentary tract of the healthy animal or man, proceeds to grow there and produce its toxins, which are absorbed, and then cause the stimulatory effect on the thyroid gland. More recent developments of the theory suggest, however, that the organism exists, not only in goitrous fæces, but also in non-goitrous fæces. Further, that it not only exists in the non-goitrous fæces of man, but also in that of goats, rats, pigeons and other animals. Most important of all, this theory has been linked up with the iodine-deficiency theory by making the organismal infection responsible, by means at present not quite understood, for producing the deficiency of iodine.

We have thus in goitre to-day two schools of experimental research which are predominant. The one is developed from the old empirical observation of the endemic coincidence; this has become the iodine-deficiency theory of the present day, largely as the result of the work of Baumann; its operation is seen in the preventive and curative work which is being achieved in the Swiss endemic areas, in America and elsewhere. The other is the organismal theory, but now so modified that while its supporters admit that deficiency of iodine in the human system is the proximate cause of goitre, they claim that the existence of such deficiency is dependent on and primarily due to the fæcal organism or organisms which have been proved to have the effect of producing goitre when administered by the mouth in culture or otherwise. According to the iodine-deficiency theory, there is a natural lack of iodine in the food and water of certain places; according to the micro-organism theory, the lack of iodine is not a deficiency natural to the food and water, but is an artificial one produced by the active intervention of fæcal organisms which have been ingested. The mechanism of production of iodine deficiency in the human system has recently been the subject of further research, and the suggestive observation has been made that certain fats and oils when taken in excess prevent the system from absorbing sufficient iodine for its needs from a diet which contains iodine in an adequate amount. Certain oils, on the other hand, such as cod-liver oil, which contain an appreciable amount of iodine, while they may exercise a detrimental effect, *quâ* oil, on the absorption of iodine, are yet—because of their own iodine content—not only incapable of producing goitre, but are even capable of preventing the development of goitre in animals fed on fæcally-contaminated food, a diet which would certainly produce goitre in the absence of some such vehicle of iodine.

The Scope of the Present Investigation.—With the object of ascertaining, if possible, whether a natural deficiency of iodine in the water of certain areas would account for the known incidence of goitre in the endemic districts, it was decided that, as part of the investigation, a direct test should be applied. This test consisted in taking a river which passes through a portion of the endemic area and tracing it up to its source in the mountains; by this direct method it was hoped to obtain valuable information on the much-debated question of iodine deficiency. It appears reasonable to suppose that if goitre occurs on a river some distance from its source, and if this goitre is due to a natural deficiency of the river water in iodine, then on tracing the river to its ultimate origin in mountain springs we shall find greater, or at least as great, numbers of persons affected with goitre at the higher levels. A river with many villages on its course is evidently the best calculated to provide the information; for this purpose the river Bagwe seemed well adapted, because not only does it traverse a large portion of the endemic area, but also there are many villages situated on it, and last of all its sources, which lie within the territory of Sierra Leone, are accessible. The results of the examination of the villages at the Bagwe source will be set out in detail in their proper sequence; it will be shown that the results obtained have importance relative to the iodine-deficiency problem.

Inspection of Population.—The total number of people who underwent examination for goitre was 2,508, of whom 1,547 were males and 961 females. Persons with enlarged thyroid were found in twenty-three villages to the number of 426, of whom 176 were males and 250 females. Not all of these cases, however, had acquired their goitre in the village where they were examined; in certain cases a definite history was obtained which proved that the condition had been acquired elsewhere. A fact which appears to require emphasis here is that Protectorate village children often travel in early youth from the village in which they are born and in which they subsequently reside. It is a not uncommon custom for mothers to take their young children back to their own villages on a visit at a period soon after the child's birth. In such cases it is not always possible to state with certainty that these children were not exposed to goitre-producing causes at their mothers' villages. As far as possible, all persons with such doubtful histories were excluded from the figures of the particular village in which they were discovered. This correction reduced the totals for classification as follows: Of thirty-seven villages examined twenty-two had cases of goitre present in a population of 2,465; among 1,532 males there were 161 with goitre, and among 933 females 222.

Relative Incidence in Males and Females.—It is seen that of 1,532 males examined 161 or over 10 per cent. had goitre, while of 933 females examined 222, that is over 23 per cent., had goitre. The difference in the totals of males and females coming to be examined was accounted for in various ways by the chiefs. Fear of the white man, fear of vaccination, fear of being operated on for goitre, occupation, and similar reasons were given. The fact that smaller numbers of women presented themselves for examination would not, however, produce any increase in the percentage of females who proved to have goitre, unless it is assumed that those females who had goitre remained for

examination in greater proportion than those who had no goitre. As a matter of fact, it is probable that the reverse was the case and that proportionately more females with goitre stayed away than those without goitre. On several occasions it was stated by the chief that women whom he knew with goitre had stayed away for fear of operation; this was verified in some villages where such women with goitre were produced late in the day after being reassured by their companions on this subject. It appears, therefore, that we may accept the large relative preponderance of females affected with goitre in the villages visited as a fact.

The findings in Sierra Leone as regards the sex incidence of goitre correspond with those in other localities where goitre has been studied. In a place where goitre exists in endemic form it more commonly affects females than males. Many reasons for such a relatively large incidence in females have been suggested; the most commonly given being physiological ones which associate increased susceptibility of the female thyroid to hypertrophy, with the temporary enlargements of the gland which accompany normal functions in the female, e.g., menstruation. That is to say, that given an adult population of males and females of the same age, equally exposed to these influences which produce pathological enlargement of the thyroid gland, the females will be more affected because their thyroid mechanism is naturally more easily disturbed than is the case with males. There is some evidence that even in animals which are living in districts where goitre is endemic there is a tendency among the females to greater thyroid morbidity. McCarrison (1914-1915) noted that in the goitrous district of Sanawar thyroid hyperplasia occurred more frequently in female than in male wild rats.

Septic Conditions as a Factor.—It is stated that thyroid enlargement may result from a septic focus in the body; it is not suggested that all septic sores, and toxic conditions and septicæmias have this effect. Curiously enough, such effect is stated to be produced usually by a septic focus situated in the tonsils, nasal sinuses, or teeth. No evidence was found of such casual relationship during the investigation. At Kaivima the personal and family history of twenty-eight cases of goitre was taken in some detail, and at the same time an examination was made and any physical abnormality noted. A septic condition of the mouth was found in eight cases; the degree of the septic condition and its frequency were not greater than that found in non-goitrous persons. While it is possible that in some cases the septic condition may have had a causative influence, it was not possible to find cases in which the influence of this cause could be estimated.

Prevention and Treatment.—The results recorded from the countries in which the prevention and treatment of endemic goitre are carried out by the supplying of iodine in some form are striking. Over a period of three years Drs. Maine and Kimball examined 10,000 girls in Akron, Ohio. Of those who had moderately enlarged thyroids and accepted treatment 79·7 per cent. showed a decrease in size of the glands; only 12·4 per cent. of those who did not accept treatment showed decrease; the totals accepting and refusing treatment being equal. In St. Gall, Switzerland, iodine prophylaxis was adopted for all the school children. In 1918 87 per cent. had thyroid; after a period of three years' iodine prophylaxis, in 1922 only 13 per cent. had enlarged thyroids.

Report on an Investigation into the Prevalence and Transmission of Human Schistosomiasis in Sierra Leone.

1. *Rectal Schistosomiasis.*—The examination of the fæces for the purpose of diagnosing this disease is attended with some difficulty among these tribes, both pagan and Moslem; to a less degree this applies also to the examination of urine. Great reluctance was shown by the natives throughout the investigation in allowing the examination of excreta. This is due chiefly to certain beliefs which these people hold concerning possible evil effects which may be produced by the person into whose possession such material comes. Fortunately, in some cases the chiefs and headmen were enlightened enough to assure their people that the white man did not possess sufficient knowledge to acquire evil power over them by such means. This assurance was effective usually to this extent, that the older and more influential people sent their young relatives to be examined. The number of persons in whose cases the examination of fæces was possible was 188, of whom 134 were males and fifty-four females. Only in one case—a female—were terminal-spined ova of *Schistosoma hæmatobium* found in the fæces, and this was possibly due to contamination from the urine, which was heavily infected. The figures are sufficiently large to show that rectal schistosomiasis due to *S. mansoni*, if it exists at all in this region, is rare; some further evidence supporting this view will be produced in the section dealing with the snails.

2. *Urinary Schistosomiasis.*—In thirty villages the urine of as many persons as possible was examined; any infected cases which had clearly acquired the disease in other localities were excluded from the figures.

3. *The Effects of Urinary Schistosomiasis on the Population.*—In many cases the disease was accompanied by definite severe symptoms, such as pain in the bladder region, in the back and over the liver; in most severe cases in adults there is an associated mental depression.

On the other hand, in many cases the existence of the disease was unsuspected by the persons affected. This does not necessarily mean that the individuals in this case do not suffer; it may simply mean that the true cause of any symptoms experienced by them is overlooked because the urine does not contain visible blood. Between the two extremes mentioned lies the vast bulk of the cases: these suffer from definite symptoms, and the disease from time to time causes sufficient pain and inconvenience to prevent the infected persons from pursuing their usual avocations with any activity.

Colonial Medical Reports.—No. 177.—Sierra Leone
(continued.)

The best evidence that the disease is troublesome to them is their readiness to submit to treatment. As soon as the severely affected persons observed that the intravenous injection of antimony resulted in relief of symptoms, as well as the clearing up of blood in the urine, numerous applications for this treatment were received. Natives do not as a rule submit themselves readily to such a treatment unless they are suffering considerable discomfort. One unfortunate thing about the treatment of schistosomiasis by this means is, that it relieves symptoms and signs rather too early. Its value as a means of general application for the eradication of the disease is thereby unexpectedly limited. For as soon as the native feels well he fails to present himself for further treatment, and no amount of explanation will convince him of the necessity for continuing the treatment. For this reason, if no other, it would undoubtedly be an unwise policy to entertain any serious hope of the eradication of schistosomiasis by this method in these large native populations.

Native Views on Schistosomiasis.—The native names for this disease are various, each tribe having a name of its own for the condition; these names were invariably translated into English by the interpreters as "red gonorrhœa." It is recognized by the natives examined that there is a "white gonorrhœa" and a "red gonorrhœa." This has sometimes led to confusion in the minds of Europeans, when the word gonorrhœa has been used without the qualifying adjective; it has surprised them to be informed by the parents that a young child is suffering from "gonorrhœa." No adequate explanation could be offered by the natives of the causes which produce "red gonorrhœa"; the problem appears to be too profound for solution by their usually acute methods of observation.

The Identification and Bionomics of the Snail or Snails which act as Intermediate Host in this Country.

An extensive list of aquatic and non-aquatic snails was collected during the three months expedition; only the aquatic forms need be mentioned here. The aquatic snails found were dissected and examined for the cercaria stage of the parasitic worm.

Ampullaria balanoidea (Gld.) was the commonest of the aquatic snails found. It was usually present in large numbers on the sandy bottom of streams and in relatively clean water. Dissection of it in various localities did not reveal infection with cercariæ of any kind. It was found very widely in all districts visited. *Planorbis* (*Hippentis*).—This was found only at Jiama (Nimmi Yemma) Konno country.

Physopsis sp.—nearly allied to *globosa* (Morel). It was found to contain cercariæ which morphologically appeared to be those of *Schistosoma hæmatobium* and which were subsequently proved to be so by means of infecting animals (guinea-pig and monkey) with them, and obtaining adult worms.

Infection of Physopsis with Cercariæ of Human Schistosomes.—The figures given show that of 1,557 specimens of *physopsis* dissected 306 had cercariæ of some kind present in their tissues. Out of the 306 there were 184 infected with the cercariæ of *S. hæmatobium*, which was the only schistosome parasite affecting the population examined. In some cases where cercariæ of *S. hæmatobium* were found other cercariæ were also present in the same snail. Again, in snails from some localities, little or no infection of any kind was found; the variable rate of infection from different localities was a very striking phenomenon.

Locality	Number of *physopsis* dissected	Numbers infected with cercariæ of *S. hæmatobium*	Per cent.
Jiama (Nimmi Yemma) ...	497	12	2·4
Jiama (Nimmi Korro) ...	200	18	9·0
Bendu	160	18	11·2
Taiko	48	8	16·6
Kaiyima	373	112	30·0
Paya	50	21	42·0

On considering the factors which result in the production of a high rate of infection in these snails, it was found that the infection rate was directly proportional to the contamination of the water supply in a village by human excreta. One section of the village goes to a spring for its drinking water. The path to this spring passes through a shallow muddy pool into which comes the water from the men's latrine situated a few yards away. From the spring a stream runs towards the village and turns sharply into a wet rice field just before reaching the pool mentioned. The spring and the upper part of the stream from it yielded no *physopsis;* the water ran on a bed of coarse sand. Lower down towards the village a layer of mud had formed on the sand and a few *physopsis* were found here. On following this stream to the rice field, where it became lost in marshy ground, *physopsis* was easily found, usually on weeds or on the underside of fallen leaves; many were in the mud and came to the surface after the mud had been trampled down.

Methods of Prevention of the Disease.—Enough has been said to show that the prevalence of the disease and the morbidity resulting from it are sufficiently great to deserve attention. It has been said that while we have in antimony a very powerful and efficient drug for the treatment of cases, it would be unwise to attempt its use on a large scale here with the idea of eradicating the disease. It appears that other means than this must be adopted, as we know that if infected snails remain the people will become reinfected.

Sanitary education is the true and practical solution of this problem here.

Colonial Medical Reports.—No. 178.—Cairo.

REPORT OF THE MEDICAL OFFICER OF HEALTH, CAIRO CITY, FOR THE YEAR 1921.

Vital Statistics.

Population.

The mid-year population of Cairo for 1921, as estimated by the Statistical Department, was 765,200, consisting of 692,057 Egyptians and 73,143 foreigners. To this population should be added that of the area around Helwân proper. This population, which has been estimated at 29,025, added to that of Cairo amounts to 794,225.

Births.

There were 36,914 births in Cairo during 1921. This total shows a still further increase on the annual totals of the last eight years, and is 930 higher than in 1920.

Deaths.

The total number of deaths which occurred in Cairo during 1921 was 24,177, which is the lowest total during the last eight years.

Infantile Mortality.

The total number of infantile deaths during 1921 amounted to 8,252, including 143 deaths of children coming from outside Cairo, which occurred in various public institutions.

The total deaths belonging to Cairo proper was, therefore, 8,109.

The death-rate for 1921 is the lowest during the last eleven years.

As in former years, the main cause of infantile deaths was diarrhœa, the total number of deaths from this disease being 3,384.

Infectious Diseases.

The total number of infectious diseases notified during 1921 was 4,759, excluding 351 cases coming from outside Cairo.

Of this total there were 1,479 cases of influenza, which only became notifiable in August, 1919. This year shows an improvement on the previous seven years.

Regarding the totals of the individual eight principal diseases, all are well below the average totals during the last eight years.

The total of other diseases amounted to 2,733. They include 1,479 cases of influenza, 384 of whooping cough, 408 of mumps, 1 of leprosy, 25 of tetanus, 232 of chicken-pox, 198 of rabies, 1 of Malta fever, 4 of encephalitis lethargica, and 1 of acute poliomyelitis.

This shows a considerable increase of whooping cough, mumps and rabies, as compared with previous years, especially as regards rabies.

Small-pox.—The total number of cases of this disease notified during 1921 only amounted to five, with one death. So that it will be seen that this total is the lowest that has occurred for many years.

Measles.—The total number of cases of measles during 1921 was 282. The number of deaths was 108.

Scarlet Fever.—The total number of cases of this disease during 1921 was 66.

Diphtheria.—The total number of cases notified in 1921 was 438. The total is the lowest (excluding 1920) as compared with the previous eight years.

Typhoid Fever.—The total number of cases notified this year was 669, which is 256 fewer than in 1920, when the total was the lowest since 1913.

Typhus Fever.—The total number of cases of this disease during 1921 was very low when compared with the previous six years, the whole amounting to 385.

The campaign, instituted during March, 1920, with a view to combat the source of this disease (and Relapsing Fever), was continued throughout 1921.

Relapsing Fever.—There were 167 cases of relapsing fever notified during the year and eight deaths.

Cerebrospinal Fever.—The total number of cases of this disease which were recorded this year was fourteen, with five deaths.

Influenza.—During 1921 there were 1,479 cases notified. The number of deaths as recorded from influenza was 110.

The number of deaths from all respiratory diseases, excluding tuberculosis, was 3,824, out of which 1,419 were from pneumonia, 2,217 from bronchitis, 27 from pleurisy and 161 from other respiratory diseases.

Of the 1,419 deaths from pneumonia 820 were of children up to five years of age, 46 from over five to fifteen years, 182 from over fifteen to thirty-five and 301 over thirty-five.

The prophylactic measures carried out during 1921 were the same as those followed in 1920.

Anthrax and Shaving Brushes.—As stated in the last annual report Law No. 21 of 1920 by Article 3 empowers the Government to prohibit entirely the importation of shaving brushes in cases where it is considered that the Certificate of Disinfection accompanying them does not sufficiently guarantee their freedom from Anthrax infection.

This article was applied in the case of Japan by Arrêté of April 7, 1921, and the importation of shaving brushes manufactured in that country is now prohibited.

Government Fever Hospital, Abbasiya

The very unsuitable mat huts which were in use for the annual summer epidemics of the past five

years have been removed, and in their place five pavilions have been erected with walls formed of asbestos-cement sheets. Two pavilions still remain to be completed.

These pavilions will be cool in summer and warm in winter.

Compound for the Hospitalization of Military Infectious Cases.—Up till 1920 little except small-pox was admitted, most other cases of the milder infectious disease occurring amongst the military being isolated in a special military infectious disease hospital. Consequent on an agreement arrived at with the military authorities it was arranged that, in future, cases of infectious disease of all kinds, except cholera, occurring amongst the military units and their families on the married establishment should be admitted to the Government Fever Hospital to be accommodated in a special section to be built by the military authorities. The building of this section was completed in 1920 and put into use in 1921.

During the year 1921 there were 1,983 admissions to the Government Fever Hospital.

The admissions consisted of 20 cases of chicken-pox, 16 of measles, 27 of scarlet fever, 4 of cerebro-spinal fever, 47 of diphtheria, 100 of mumps, 688 of influenza, 18 of erysipelas and 9 of typhoid. In addition to these, 373 cases were sent to hospital under a mistaken diagnosis of infectious diseases, 37 persons were admitted under observation in whom no disease of any sort manifested itself and 91 mothers of young children and other persons accompanying patients were accommodated. The 373 cases sent to hospital under a mistaken diagnosis of infectious diseases were found on examination to consist: 40 of gastro-enteritis, 61 of malaria, 33 of pneumonia, 7 of bronchitis, 27 of tuberculosis, 3 of whooping cough, 45 of tonsilitis, 6 of dysentery, 9 of rheumatism, 6 of various skin diseases and 136 other cases of a most diverse nature consisting of syphilis, gangrene, tumour of brain, heart disease, &c.

The admissions from the eight principal notifiable diseases (measles, scarlet fever, diphtheria, typhoid fever, typhus fever, the relapsing fever and cerebro-spinal fever) were 647.

There were 159 deaths in the hospital during 1921.

Of these, 51 were due to typhus, 35 to typhoid, 1 relapsing, 6 to influenza, 15 to diphtheria, 1 to chicken-pox, 4 to cerebrospinal fever, 2 to erysipelas, 2 to tetanus, 7 to tuberculosis, 6 to enteritis and 12 to pneumonia.

In addition, there were 17 deaths amongst patients sent in under mistaken diagnosis of infectious disease and whose condition on arrival did not permit of a refusal of admission.

There were three concussion of brain, 1 septicæmia, 7 senility, 1 nephritis, 3 enteritis, 2 encephalitis and 1 hydrophobia.

Included amongst the third-class admissions were 111 sick convicts from Cairo Prisons. Of these, 6 were suffering from typhus, 10 from typhoid, 62 from influenza, 5 relapsing, 11 mumps, 2 paratyphoid, 2 tuberculosis, 1 enteritis, 1 septicæmia, 1 malaria, 1 dysentery, 2 erysipelas, 4 pneumonia and 1 glanders.

Of the convict patients 3 died, death being due to typhoid fever.

Vaccinations.

During 1921 there were 32,855 vaccinations carried out by the Medical Officers of the Inspectorate and Districts. 30,361 of these were primary vaccinations, of which 29,675 were on native children and 686 on children of foreign parentage.

The remaining 2,494 were secondary vaccinations of contacts of small-pox or of persons voluntarily applying for this.

Colonial Medical Reports.—No. 179.—Cairo.

REPORTS AND NOTES OF THE PUBLIC HEALTH LABORATORIES, CAIRO.

I.—The History and Progress of Anti-Ankylostomiasis and Anti-Bilharziasis Work in Egypt.

Historical Review on Ankylostomiasis and Bilharziasis in Egypt up to 1913.

Introduction.

Up to 1913, when a scientific advisory committee was formed in the Department of Public Health to advise on ankylostoma work in the provinces, no united effort had been made to check or ameliorate bilharzia or ankylostoma infections in Egypt.

At various periods in the past there were individual efforts to study and investigate these diseases in Egypt, resulting in brilliant discoveries regarding their ætiology, epidemiology and pathology. It is safe to conclude that our present knowledge It is safe to conclude that our present knowledge of these diseases is mainly a combination of the work done in Egypt at different periods with some additions from abroad. Outstanding names amongst the investigators are: Bilharz, Griesinger, Pruner and Looss, the German investigators; Leiper, Sandwith, Symmers and Madden, amongst the English, and Sonsino, the well-known Italian parasitologist. It

is to the efforts of these investigators that the country owes a deep sense of gratitude in affording a sure basis for the proper understanding of these diseases as a necessary step to combating their ravages.

Ankylostomiasis in Egypt.

Ankylostomiasis is endemic in Egypt. There is no evidence of its being introduced from other countries, and thus it was probably present in ancient times. A disease resembling ankylostomiasis is said to have been depicted by the ancient Egyptians, but it is yet doubtful if its causal agent was recognized at those remote periods.

Ankylostomiasis worms were first found in Egypt by Pruner in 1847 at the autopsies of Egyptians in Cairo. Till that time these parasites were considered as harmless organisms. It was Bilharz (1853) and Griesinger (1854), both teachers at the Cairo Medical School, who first connected the parasites with the extremely prevalent chlorosis noted in Egypt. The disease, for lack of ætiological factor, was then known as "Egyptian Chlorosis," or "Egyptian Anæmia." It was regarded by Bilharz and Griesinger to be the cause of more than one fourth of all deaths in Egypt.

The valuable observations of Bilharz and Griesinger were not followed up, but the interest in this disease was revived by Sonsino in 1878. This was followed by a period of great activity, both in the clinical aspects of the disease carried out by Sandwith and in the zoological aspect of the parasite and its life history by Professor A. Looss.

The researches of Professor A. Looss resulted in his discovery of the dermal method of infection by ankylostoma larvæ, one of the most far-reaching discoveries in parasitology in recent years. His monographs on the anatomy and life history of *Ankylostoma duodenale* published in the records of the School of Medicine, Cairo, are outstanding landmarks in the history of the disease.

In the early years of the present century an effort was made by Sandwith to treat ankylostomisas cases at Qasr el 'Aini Hospital, Cairo, on a large scale.

Up to 1913, however, no exact knowledge as to the incidence of ankylostomiasis in Egyptian villages was available. It was only indirectly inferred that the infection was widespread, judging from the incidence of infection in cases seeking medical advice at Qasr el 'Aini Hospital from different provinces of the country.

Bilharziasis in Egypt.

Bilharziasis has been traced definitely to ancient times. Ruffer (1910) demonstrated bilharzia ova in sections of kidneys from ancient Egyptian mummies of 1250-1000 B.C. Hæmaturia was one of the diseases recorded by the ancient Egyptians and prescriptions for the treatment of the condition have been discovered in medical papyri. It is, however, doubtful if the parasitic nature of the disease was recognized.

It was Bilharz in 1852 who first discovered the bilharzia worms in the portal system and connected them with the endemic hæmaturia common amongst the Egyptians. Subsequent to Bilharz's discovery several attempts were made to discover the life history of the bilharzia worms and of the method of infection of the human host. Sonsino, from 1874 to 1884, examined a large number of the snails of Egypt for the evidence of an intermediary stage of bilharzia worms. He was unsuccessful in his attempt, although his researches were valuable in determining other cercariæ in Egyptian fresh water mollusca. The subject was next taken up by Looss, who endeavoured for many years to discover the intermediary host, which he suspected to be a mollusc, but he was also unsuccessful. This led him to infer that no molluscan intermediary host was essential in the bilharzia cycle and that man himself acts both as a definitive and intermediary host, but his experimental attempts at proving this inference gave negative results.

The question of finally elucidating the life history of the bilharzia worm was left to Leiper, who in a series of brilliant and well thought out investigations carried out in Egypt between 1915 and 1918 definitely elucidated the life history. He was also able to prove that the urinary and intestinal varieties of the disease are due generally to two different species: *Schistosoma hæmatobium* and *Schistosoma mansoni* respectively, thus finally supporting the views of Sambon.

Up to the time of the discovery of the life history of the parasite no curative treatment was known. MacDonagh (1915), in his book on the "Biology and Treatment of Venereal Diseases," stated that he had succeeded in curing cases of bilharzia infection with tartar emetic. This statement attracted no attention, and it was the detailed reports of Christopherson upon the treatment carried out at the Khartoum Civil Hospital that introduced the drug into general use.

No exact data as to the extent of infection with bilharzia in Egypt were available before 1913, although it was concluded, from the high percentage of incidence among patients attending general hospitals, that the disease was possibly the most widespread serious malady in Egypt.

The following records are, however, significant:

Larry (1812-1817), in his "Mémoires de Chirurgie Militaire et Campagnes," stated that the symptoms of the disease, especially "hæmaturia," were frequent amongst the French troops during the Napoleonic expedition to Egypt (1799-1801).

Griesinger (1866) recorded that in 32 per cent. of 363 autopsies at Cairo he found evidence of bilharzia infection.

Sonsino (1874), in a series of 91 autopsies in Egypt, reported the incidence of bilharzia infection in 46 per cent.

In 1894 Kaufmann recorded from 500 autopsies that of 368 males 40 per cent. and of 131 females 11·5 per cent., *i.e.*, a general average of 33·3 per cent. showed evidence of bilharzia infection.

Colonial Medical Reports.—No. 179.—Cairo *(continued.)*

In 1910 Ferguson stated that his observations, based on considerably more than 1,000 post-mortem examinations at Qasr el 'Aini Hospital, revealed the presence of bilharziasis in no less than 40 per cent. of Egyptian male subjects between five and sixty years of age. Ferguson, as a result of post-mortem examination of 500 male subjects, ascribed the cause of death in 8 per cent. of all cases to the effects of severe bilharzial infection.

THE INAUGURATION OF THE ANTI-ANKYLOSTOMIASIS CAMPAIGN.

The first serious effort to check the ravages of ankylostomiasis in Egypt was undertaken by the Department of Public Health towards the end of 1913 on the initiative of Lord Kitchener. In his annual report of 1913 Lord Kitchener, referring to ankylostomiasis and bilharziasis, stated: " . . . . it is high time that serious steps should be taken to prevent the continuity of infection that has been going on so long in this country."

A Scientific Advisory Committee was formed consisting of the following: Professor Arthur Looss (president), Dr. A. F. Ferguson (secretary), Dr. C. Todd, Dr. H. B. Day and Dr. W. Hastings (members).

The function and purpose of the committee was to co-operate as a scientific advisory body with those directly responsible for dealing with ankylostomiasis in Egypt.

An ankylostomiasis annexe was established at Qalyûb. This was practically a travelling tent hospital with accommodation for 100 in-patients. The organization was carried out on lines similar to those on the Travelling Ophthalmic Hospitals in Egypt. The treatment was entirely free and voluntary, people who could afford treatment in their own houses were not admitted.

The whole field work was placed under the direction of Dr. MacCallan, Director of the Ophthalmic Hospitals of the Department of Public Health.

Modification in the Scope of the Work.

In addition to combating ankylostomiasis, it was found to be advisable to add to the work of the ankylostomiasis field hospitals the duty of collecting data as to the incidence and symptomatology of bilharziasis and pellagra.

In order to appreciate the good cause of such an addition, the endemic diseases of the country must be referred to. In Egypt there are four widespread diseases causing incapacity, chronic illness and death of a high percentage of the population. These diseases are bilharziasis, ankylostomiasis, ophthalmia and pellagra.

Ophthalmia was the first disease to be combated on a large scale, thanks to the magnificent initial gift of Sir Ernest Cassel of £E.40,000 the income of which was to be devoted to the relief of eye diseases in Egypt. The Egyptian Government has since undertaken the organization of ophthalmic hospitals, both travelling and stationary, all over the country. The value of the good work done is highly appreciated throughout Egypt, and the ophthalmic hospitals now represent an integral part of the Department of Public Health.

Bilharziasis and pellagra, at the time of the inauguration of the work (1913), were both diseases the means of spread of which were unknown and no certain cure for which was available. Ankylostomiasis, on the other hand, was curable in a high percentage of cases, although there was considerable difference of opinion as to the efficiency of the many drugs advocated. The method of infection, thanks to the work of Looss, was known, although how it occurred in nature and the details of prophylaxis were still left to be worked out.

1.—REPORT ON THE CAMPAIGN FROM DECEMBER, 1913, TO APRIL, 1915.

To the work conducted in Egypt there were two main features: *hospital work and survey work.* The first was directed to relieving the sufferers, the second to locating the areas of heaviest infection and the danger points in those areas from which the infection was spread. The survey work also attempted incidentally to establish, by clinical examinations, the degree of prevalence in Egypt of two other diseases: bilharziasis and pellagra. Travelling tent hospitals were established at convenient centres to which the inhabitants were invited to come for diagnosis and treatment. Infected persons were usually kept in the hospitals as in-patients until a complete anthelmintic course had been administered. The hospital work was confined to two provinces, Qalyubîya and Sharqîya.

The Rockefeller Foundation Grant.—The Director-General of the International Health Commission of the Rockefeller Foundation, Mr. Wickliffe Rose, visited Egypt in February, 1914, and made a careful study of the experimental arrangements for treating ankylostomiasis. As a result of his recommendations, the commission granted a sum of 30,000 dollars (£E.6,000) on the condition that the Egyptian Government paid an equal amount. Thus the sum of £E.12,000 was available during the financial year April, 1914, to March, 1915. The magnificent gift of the Rockefeller Foundation enabled the proper carrying out of the campaign on a larger scale than was originally anticipated.

Hospital Work.

The number of persons microscopically examined for ankylostoma infection during the period from December 13, 1914, to March 31, 1915, was 29,281. Of these 10,876 were found infected. The number of persons admitted to the hospitals was 11,280 of those found infected. 10,694 of those admitted were given full treatment and 450 were discharged before the completion of the full course of treatment.

Microscopic Examination for all Parasitic Worms.—In addition to the microscopic examinations for ankylostomiasis, specimens of urine were examined microscopically for bilharziasis. Other ova of intestinal parasites were incidentally recorded in addition to ankylostoma ova. 17,987 specimens of fæces were microscopically examined. The findings were as follows: 10,876 showed ankylostoma ova, 3,543 showed oxyuris ova, and 3,067 showed ascaris ova.

10,400 specimens of urine were examined for evidence of bilharzia infection, and bilharzia ova were detected in 5,821 of the cases.

Clinical Examinations for Diseases other than Ankylostomiasis.—Patients admitted to the hospitals with ankylostomiasis were subjected to microscopic examinations for bilharziasis and albuminuria and to clinical examinations for pellagra, œdema, enlarged liver, dilated heart and enlarged spleen. The total number thus examined was 10,397.

Hæmoglobin Index of Ankylostomiasis Patients.—Hæmoglobin tests (Tallquist) were made of the blood of 9,696 patients when admitted to the hospitals for treatment for ankylostomiasis. The average percentage of hæmoglobin on admission was 44. The average percentage of hæmoglobin of 4,031 patients, one month or more after treatment, was 49.

The majority of the cases treated for ankylostomiasis were between the ages of eleven and forty years.

Methods of Treatment for Ankylostomiasis.—(1) Treatment by thymol, three doses. *First day of admission*: Detection of ova in fæces. Physical examination and clinical note taking magnesium sulphate, two ounces in evening. Diet: Dinner only at midday.

Second, third and fourth days: Thymol, four grammes (sixty grains) in cachets; magnesium sulphate, two ounces; diet, dinner and supper.

Fifth day: Diet, breakfast only; discharge. (2) Treatment by oleum chenopodii.

This treatment was applied to children or others who were unable to take thymol cachets. *First day*: Midday meal; magnesium sulphate. *Second day*: 7 a.m., adult dose oleum chenopodii twenty-four drops on sugar; 9 a.m., adult dose oleum chenopodii twenty-four drops on sugar; 11 a.m., an adult dose castor oil seventy grammes, chloroform water forty-five drops. *Third day*: Repeat treatment if no ill-effects. *Fourth day*: Repeat treatment if no previous ill-effects. *Fifth day*: Discharge.

N.B.—(1) If there are symptoms of intoxication after the first dose of oleum chenopodii the treatment should be abandoned and a careful note made as to the signs of intoxication observed.

(2) If an evacuation of the bowels has not occurred by 1 p.m. an enema of soap and water should be immediately given. This should be followed by sodium sulphate thirty grammes whether or not the enema has been successful.

Survey Work.

Survey work was begun on October 1, 1914, and contined to April 8, 1915, when both hospital work and survey work in Egypt had to be abandoned because of the European War. The aim of the survey was to determine the extent and degree of infection with ankylostomiasis and to locate the danger centres from which the disease was spread. Incidental observations were made concerning the incidence of pellagra and bilharziasis. Two of the fourteen provinces of Egypt were selected for the survey. Sharqîya was selected as a typical province of Lower Egypt and Asyût as a typical province of Upper Egypt.

During the survey only males were examined owing to the difficulty in inducing females to submit themselves for examination. The survey of rural areas in the Province of Asyût was based entirely upon the examination of boys, who could be examined with less difficulty than men. The difference of incidence of infection amongst boys and men was found to be appreciable only in the town inhabitants, where it was the custom to examine 100 men and 201 boys.

Comparison of Infection.—Population of the two provinces surveyed, 1,756,230; number examined 10,153; number infected with ankylostomiasis, 5,175.

Infection with ankylostomiasis is more evenly distributed throughout the Sharqiya Province than throughout Asyût.

Method of conducting the Survey.—For securing the specimens the custom was to request the village headman by telephone, one day in advance, to have the required number of boys or men on hand at his house at a fixed hour on the following day. Each person was supplied with a tin box in which, in the presence of a village watchman, he had to place a specimen of his fæces. The boxes were later returned personally to the collector, who numbered them serially and then entered them in survey cards, one for each individual, bearing the number of the box, the name of the village district in which he lived, and the clinical data relative to other diseases.

Technique of Microscopic Examination.—From each specimen box a portion, the size of a bean, was taken and placed in a test-tube with water and thoroughly shaken. The emulsion thus formed was strained through coarse gauze into a centrifuge tube, one end of which had been previously corked, and twenty-four such specimens were placed in correspondingly numbered sections of the centrifuge. After rotation, the supernatant fluid was drained off, and by removing the cork the last drops were obtained. This was divided into two parts, mixed with an equal quantity of methylene blue, and spread on two slides. Search was then made for ova under a microscope equipped with a travelling stage. No specimen was considered negative until two slides had been examined each for the period of five minutes. When ova were

found by one physician, the fact was verified by the second physician looking down the other's microscope.

A test was carried out on seventeen specimens examined by the centrifugal method which were cultivated for larvæ. Two, which were positive to the microscope, gave a negative result on cultivation, and one which had been found negative was found positive by cultivation. Recent work not yet published on cultivation of ankylostoma fæces showed that 16 per cent. of the stools during summer in Egypt maintain an acid reaction, and in these no larvæ reach maturity. The larvæ die directly after hatching. The addition of calcium carbonate in small amounts to fresh stools ensures the success of cultivation.

The results of the survey represent the absolute minimum of infection. In view of the large number of specimens examined the results cannot be absolutely accurate, for a certain number of the eggs will escape detection. Another source of error may be found in the unsuitability and insufficiency of specimens supplied by boys. For example, out of twenty such specimens taken at random, five were in such small quantity as to prejudice the result.

Hæmoglobin Index.—In the entire survey work in Egypt, 2,923 specimens of blood were tested for hæmoglobin by the Tallquist scale with an average index of 61 per cent.

II.—Prevalence of Pellagra.

Only a cursory examination for pellagra symptoms was made, i.e., dermatitis on face, neck, hands and feet and enlarged parotids. The survey was conducted during the autumn or winter, when pellagra was seldom prevalent, so that the disease was not diagnosed unless it was very obvious.

Of the 10,153 persons examined, 250 were recorded as showing pellagra symptoms. Amongst 4,411 persons examined in Asyût, 89 were recorded as pellagras. Of the total of 543 prisoners, 14 were recorded as pellagras.

III.—Prevalence of Bilharziasis.

A crude estimate of the prevalence of bilharziasis of the bladder only was obtained in both provinces by listing as infected all those who stated that they had noticed blood in their urine. No microscopic examination of the urine was made. There is no doubt that that procedure grossly under-estimated the real condition of affairs.

Of the 10,153 persons who were questioned as to hæmaturia, 2,073 were classed as infected.

Presence of Birkas.—It was shown that the presence of *birkas* (ponds) does not bear an important relationship to the spread of ankylostomiasis.

Resumption of the Campaign in 1919.

The extension of hostilities to the Near East and the beginning of the Dardenelles Campaign unfortunately paralysed much of the work in Egypt, as a great demand was made on hospital accommodation for British wounded.

The work in the ankylostomiasis tent hospitals was discontinued on April 8, 1915. All the equipments were despatched to Alexandria together with all ophthalmic hospitals to form the Stationary Public Health Department Hospital at Glymenopoulo, of 650 beds, for the care of wounded soldiers.

Meanwhile, all ankylostomiasis work in Egypt was indefinitely suspended. When things returned to normal during the end of 1919, Professor Day, one of the original members of the Ankylostomiasis Consultative Committee revived the interest in combating this disease. In view of the discovery by Christopherson at Khartoum in 1918 of tartar emetic as a specific cure for bilharziasis it was thought advisable to include treatment of bilharziasis in the programme of the ankylostomiasis annexes.

Upon the suggestion of Professor Day an annexe was attached to Qasr el 'Aini Hospital under his direct supervision. This annexe was useful in establishing the principles of treatment to be carried out and in acting as a teaching centre for the physicians to be detailed for such work in the provinces.

Routine followed at the Provincial Ankylostomiasis and Bilharziasis Annexes.

Registration of Patients.—(1) A nominal daily roll is entered in a register book giving the name, age, sex and address of patients, a serial number being assigned to each patient. (2) An attendance card is given to each patient, to be presented whenever he returns for treatment or re-examination. (3) A treatment card is assigned to each patient; ankylostomiasis cards are yellow and bilharziasis ones red; the treatment is entered on the cards, together with the result of examination. (4) Index cards are arranged alphabetically according to the patients' names for identification in the event of a patient losing his attendance card.

Ankylostomiasis Division.—On registration the patient is given a bed pan into which he passes a stool for microscopical examination. Ankylostomiasis cases are seen by the medical officer, who takes a drop of blood for estimation of the hæmoglobin and enters the result on the treatment card. Patients who are too weak for out-patient treatment are admitted into the general hospital.

The treatment is as follows: oil of chenopodium is put in gelatine capsules, each containing 0·5 c.c. The ordinary dose for an adult is 1·5-2 c.c. (three to four capsules). The patient, who has been given a purge the previous evening, is given two capsules in the morning, sent to lie down for one and a half hours, when another one or two capsules are given. One hour after this last dose castor-oil (30 c.c.) is given. When the bowels have acted the patient is allowed to go home. He is instructed to return in about four days, when the treatment is repeated. He is usually supplied with an iron and arsenic

mixture to take for one week, and instructed to return. At his third visit the treatment is again repeated, another bottle of iron mixture is given to him and he is instructed to return after two weeks for re-examination.

Thymol is given in cachets after being well ground up in a mortar and mixed with an equal amount of sodium bicarbonate. Each cachet contains 0·5 gramme of thymol. The adult dose is 3 grammes (6 cachets). A saline purge should precede and follow thymol treatment. Three treatments are given in the same way as the chenopodium treatment.

Patients found on microscopic examination to be harbouring *Tænia saginata* or *Ascaris* are given the appropriate treatment.

Patients found to be harbouring both ankylostoma and bilharzia worms are treated first for ankylostomiasis, and after these parasites have been expelled, tartar emetic is given. It was found that such patients do not recover well from ankylostoma anæmia if a depressant drug (antimony) is given at the same time.

Bilharzia Division.—At the first attendance the patient is requested to furnish a specimen of urine or stool, according to the symptoms of the case.

Selection of Cases.—Pregnant women, patients obviously unfit, as well as cases of pyuria without living bilharzia ova, are not given tartar emetic.

The Drug used.—Sodium antimony tartrate is the drug generally used. In expert hands it is safe to use a small syringe (2 c.c.) and 6 per cent. solution, i.e., 1 grain in 1 c.c., the injections being made directly into the vein.

Should any antimony solution escape into the tissues, it causes immediate burning pain. If this happens the fluid is aspirated by withdrawal of the piston and hot fomentations applied. Such accidents are rarely met with in the annexes as a result of the experience gained by the medical officers.

Dosage and Course.—For an adult the routine course consists of twelve injections given every alternate day or three times a week, not counting Fridays. For children and women, smaller doses are required, the full dose being 1¼-1½ grains. The dose should be reduced if persistent giddiness or repeated vomiting occurs.

The Use of Emetine.—This drug is used for young children and others when it is found impossible or unwise to attempt an intravenous injection. Emetine can be given subcutaneously, but not more than 1 or 1½ grains should be injected into one site.

Precautions.—(1) Antimony solution must be made in sufficient quantity and sterilized properly. One bottle only should be opened at a time, and should not be kept more than three days. (2) Patients must be inspected after having the injections and any symptoms noted. (3) Patients should be informed that the medicine has a weakening effect and that they must not try to do as much work as usual while undergoing treatment.

Patients must be warned when beginning the course of injections that they must undergo the full treatment for four weeks, otherwise they will not be cured and the disease will return. After having taken eleven injections, the patient's urine is examined and the result recorded. After finishing the course the patient is told to return for re-examination in three months' time. Cases of pyuria after finishing the tartar emetic course may be injected with urotropine.

Laboratory Work.

Examination of Stools.—With a little experience smears can be examined without a cover slip. If it is thought advisable to use a cover slip no pressure should be exercised as it ruptures the bilharzia ova. The type of bilharzia ova found should be entered on the patient's card.

Stools of patients suspected to be suffering from ankylostomiasis are examined by the smear method. If no ova are detected the floatation method must be used.

A small portion of the fæces, the size of a bean, is emulsified in a saturated solution of ordinary salt (NaCl) by shaking vigorously in a stoppered bottle or test-tube. This emulsion is then filtered through a small copper wire sieve (100 meshes to the inch) into a conical Erlenmeyer flask, which is then filled to the brim with saturated salt solution. This is left to stand at least fifteen minutes, during which time the ova will have risen to the surface. The top layer of fluid is removed by dipping under the surface with a wire loop and tapping it off on the centre of a slide. Three or four dips will remove the surface layer. Do not spread out the fluid too much. Examine under the low power of the microscope.

Any ova will be readily seen, as most of the fæcal material has been removed. Remember that the ova are floating on the top of the fluid, which must be focused, and not on the surface of the glass as in ordinary preparations.

Examination of Urine.—With a fine pipette transfer a drop or two of the deposit from a conical urine glass on to a slide. There is no need to use a cover glass. Bilharzia ova are easily detected under a low power of the microscope. When bilharziasis is suspected on clinical grounds but no ova are to be found in an ordinary examination made as above, the urine is centrifuged and the deposit examined. In re-examination the state of the bilharzia ova must be noted. Living ova are clear, with refractile miracidia inside, the organs of which are easily seen. Dead ova are discoloured, shrunk, with a granular content. They do not hatch living miracidia when put into water.

Report on the Work of the Ankylostomiasis and Bilharziasis Annexes during 1920.

The number of patients examined and treated at the annexes during 1920-1923 is 115,036.

Bilharziasis.—An intensive course of tartar emetic injections, 4-5 in number (a total of 8-9 grains), was found to be sufficient to kill the ova if given in the first ten days. The late results of of the cases were unsatisfactory.

Colonial Medical Reports.—No. 179.—Cairo (*continued.*)

Treatment of bilharziasis with emetine, introduced by Diamantis and Erian, was given a trial and was found to be effective. The high cost of emetine militates against its routine use for out-patients; but it is a most useful alternative to use under certain conditions such as: (*a*) For young children or others whose veins are too small or inconspicuous for intravenous injections; (*b*) For patients who exhibit an intolerance for tartar emetic or where an error in technique has resulted in abscess; (*c*) For cases of bilharzial dysentery complicated by a nœbiasis.

The regular course consists of twelve injections containing 22·5 grains of tartar emetic.

Three injections a week on alternate days was the routine course. An analysis of the results shows that both the rapidity of effect and permanent cure are less dependant on the total amount of antimony given than on a regular tri-weekly sequence of injections.

Sodium antimony tartrate was substituted during the year for the potassium salt. On the evidence at hand there does not appear to be much difference in toxicity or effect.

A great many experiments were carried out in the hope of finding a substitute for antimony. Of the metals, copper gave satisfactory results *in vitro*, but though used in fairly large doses on patients (after testing on animals), only a very moderate effect was produced on the ova.

Cases with advanced bilharzial infection with septic urinary apparatus are not relieved by the tartar emetic course. Calcified ova continue to reappear in the urine by ulcerating through the mucous membrane.

It was observed that vomiting and coughing were less marked when sodium antimony tartrate was substituted for the potassium salt.

Nocturnal enuresis in children was noticed to be sometimes an early sign of bilharziasis.

One death occurred as a result of tartar emetic injection. The subject was a girl of fourteen years who had received eight injections without any symptoms. After the ninth she coughed a while and then felt better. She left the tents in a good condition, but in the same afternoon was brought to the hospital in a collapsed condition and died that night.

Compounds of bismuth were tried in bilharziasis treatment with some mild cases, which were cured, the ova being killed. More active infections were much less affected. The drug was not considered as a satisfactory substitute for antimony in this disease.

Two patients developed jaundice after the course of sodium antimony tartrate.

Two patients died after leaving the annexe in apparently good condition.

One girl, after receiving the seventh injection, was seized with convulsions, vomiting and diarrhœa the following day; died six hours after the appearance of these symptoms.

Ankylostomiasis.—As one dose of anthelmintic is beneficial in ridding the patient of a great proportion of the parasites, it was recommended that oil of chenopodium (or thymol) should be administered to every patient suspected of ankylostomiasis at the first visit without waiting to examine his stools beforehand.

Oil of chenopodium was almost the only drug used as a vermicide.

Carbon tetrachloride was under trial. At first it was given in doses of 6 c.c. (adult) and 4 c.c. (children), mixed with an equal dose of castor-oil. It was later given pure in doses of 4 c.c. and 3 c.c. respectively.

ANKYLOSTOMIASIS AND BILHARZIASIS CASES TREATED AT THE GOVERNMENT GENERAL HOSPITALS.

Cases suffering from bilharzia or ankylostoma infection are admitted into the Government General Hospitals, which exist all over Egypt. It is the rule at these hospitals to admit only the severely infected cases. Mild cases are generally treated as out-patients.

It is not safe to conclude that the number of cases admitted into any of these hospitals can be taken as index of the incidence of infection in the neighbourhood because many factors influence the admission of patients into these hospitals. The accommodation available, the railway facilities in the district, the presence of an ankylostomiasis and bilharziasis annexe in the neighbourhood, affect the number of admissions into the general hospitals.

The sudden increase in the number of cases of bilharziasis admitted during 1921 (2,219) over the number admitted during 1920 (655) marks the generalized adoption of tartar emetic treatment in these hospitals.

The number of ankylostomiasis cases treated in the Government General Hospitals during the period of 1914-1921 is 1,724, and of bilharziasis 2,219.

ANKYLOSTOMIASIS AND BILHARZIASIS PROPAGANDA.

In combating ankylostomiasis and bilharziasis in Egypt success cannot be obtained without a hearty co-operation of the people, and this cannot be enlisted unless the inhabitants realize the ravages brought about by these diseases and how infection could be avoided.

In a country where the majority of the inhabitants are illiterate the task of educating them in this direction is not an easy one, as it has to be attempted on a large scale. Lecturing in a simple colloquial language, demonstration with the aid of simple diagrams, and the distribution of leaflets amongst the villagers were attempted with a certain measure of success.

The fact that bilharziasis can now be cured by the newly discovered injections of tartar emetic is familiar to the inhabitants. The main reason preventing the "fellah" (peasant) from ridding himself of the disease is his inability to pay for private treatment, and an annexe established for free treatment anywhere needs no advertising.

From the beginning it is crowded with patients from the surrounding districts. Some patients have sometimes to remain two or three days waiting their turn to be examined and treated. Once the distressing symptoms are abated patients, unfortunately, discontinue treatment, although they are urged to receive the full course.

As the "fellah" is totally ignorant of the means of protection against infection several posters illustrating the danger of promiscuous defæcation were distributed and the danger of polluting the small water streams was especially pointed out.

The habit of defæcating near water courses is common in Egypt and cannot be easily stopped as the Mohammedan religion orders the washing of urethral and anal openings after urination and defæcation. The "fellah" has therefore to go to the nearest collection of water whenever he feels the necessity of micturition or defæcation.

The idea of washing is certainly a hygienic one, but it is only the pollution of the streams which is most objectionable. Such pollution is definitely forbidden by religion as it is dangerous to human health and life and it is absolutely necessary to convince the people of the extreme necessity of stopping it. This washing could be easily substituted by taking a small amount of water in a can or bottle, defæcating on dry ground, washing and burying the excreta. The danger, at least as far as bilharziasis is concerned, will be checked.

II.—Carbon Tetrachloride as an Anthelmintic in Ankylostoma Duodenale Infection.

During 1923 carbon tetrachloride was given a fair trial as an anthelmintic at Qalyûb Ankylostoma Annexe. Fifteen beds were set aside for patients undergoing treatment. After a preliminary trial the drug was given as a routine for outpatients. Careful microscopic examination preceded and followed the treatment and records were kept. The drug was administered to more than 4,000 ankylostomiasis cases. One death, which could not be ascribed to the action of the drug, occurred during the period. The patient on admission was suffering from heart failure, œdema of the legs, and ascites. It is unfortunate that a post-mortem could not be performed.

About one half of the cases treated with the drug returned for re-examination, once or more than once after a lapse of one week or more. It is upon the re-examination of 1,000 of these cases that the following report is based. Various modifications of the mode of treatment and dose given were tried for comparison to arrive at the most efficacious and at the same time the least troublesome method.

Properties of Carbon Tetrachloride.

Carbon tetrachloride (CCl^4) was discovered by Regnault in 1839, who prepared it by the action of chlorine on chloroform in sunshine.

It is a transparent colourless liquid with a pungent aromatic odour. It is a heavy fluid having a specific gravity of 1·63 and is highly volatile; its boiling point is 76·7° C. and is non-inflammable.

Carbon tetrachloride is soluble in alcohol and ether; in water it is soluble to the extent of 1 in 1,250 only. It does not mix with water but forms a distinct layer at the bottom of the vessel containing both.

Carbon tetrachloride dissolves a large number of organic substances, especially those of fatty nature, and it is for the latter reason that it has a wide application in the arts. It has been used as a fire-extinguisher. When prepared on a commercial scale it generally contains, as impurities, small quantities of carbon bisulphide (CS_2) and carbonyl chloride (phosgene $COCl_2$), one of the poisonous gases employed in the Great War. When used for medicinal purposes it should be free from these impurities.

Medical Uses of Carbon Tetrachloride before its Recent Introduction as Anthelmintic.

Carbon tetrachloride was first introduced by Tuson in 1843 as a lotion to be applied externally to cancerous growths. It was given internally in doses of four drops three times a day in gout.

Carbon tetrachloride was used as an anæsthetic, but its general use was given up as a result of a statement by Simpson that it was more depressant to the heart than chloroform.

During 1909, a woman 29 years old, a subject of status lymphaticus, collapsed while being shampooed with carbon tetrachloride and died.

It was used during the war for cleansing the edges of wounds.

During 1920, a girl employed in painting balls with a paint containing carbon tetrachloride suffered from vomiting after meals, headache and anæmia. Frequent inhalation of carbon tetrachloride was reported to cause jaundice.

On the whole, up to a few years ago, carbon tetrachloride was a little-known drug with a conflicting medical evidence as to its therapeutic value.

Introduction of the Drug as an Anthelmintic.

The anthelmintic value of carbon tetrachloride, especially in hookworm infection, was discovered by Maurice C. Hall, Senior Zoologist in the United States Bureau of Animal Industry. Humanity is indebted to the discoverer for this valuable remedy. The drug was first administered to dogs infested with hook-worms in doses of 0·3 c.c. per kilo of body-weight. It was found to be more effective than any other anthelmintic that was hitherto used. It was found to be safe, giving rise to no evident symptoms or post-mortem lesions.

Hall tried the effect of carbon tetrachloride on himself, taking 3 c.c. without any precaution as to food, with no ill-effects.

All the cases recorded were suffering from ankylostomiasis due to *Ankylostma duodenale* infection. No *Necator americanus* infection has yet been recorded in Egypt.

Examination of the Stools.—All stools were prepared by the flotation technique. Concentrated common salt solution was used. By this means detection of cases with mild infection was ensured.

Method of Administration.—Carbon tetrachloride was given in water. As has been mentioned before, the drug is not soluble and does not mix with water. The addition of water increases the volume of the dose and makes it easier to drink. Carbon tetrachloride can be given in gelatine capsules. These must be fresh to ensure their digestion. The method was tried but was given up on account of its expense. The intention was to find out the best method to be used on a large scale in campaigns directed to combat ankylostomiasis. The agricultural class to whom the drug was administered never complained of its taste. It is even thought that the sharp taste of the drug is a recommendation to it. To delicate patients or well-to-do people the drug can be given in capsules.

Dosage.—Carbon tetrachloride was given to adult patients in doses varying from 1 to 10 c.c. With a dose of less than 4 c.c., 50 or more per cent. of the patients revealed ova in their stools when re-examined, seven to fourteen days after treatment. This was the case whether the patient was given a purgative before, after, or both. For this reason the administration of doses less than 4 c.c. was confined only to patients under fifteen years of age, as these caused less nausea and vomiting than bigger doses. On the whole the patients were not inconvenienced by taking such doses.

On the other hand, doses above 7 c.c. for an adult were frequently accompanied by nausea, colicky sensation in the abdomen, burning feeling in the epigastrium, and vomiting. The symptoms were not serious in character and disappeared in twelve hours. As no distinct increase was noticed in the percentage of cures on the administration of such big doses, their use was discontinued early in the work.

Five c.c. was found to be the optimum dose giving the least symptoms and comparatively good results. All cases above 15 years of age were given that dose.

Children were given the drug according to the following table: from 5 to 8 years 2 c.c., from 9 to 11 years 3 c.c., from 12 to 14 years 4 c.c. Debilitated individuals were given comparatively smaller doses. The amounts given to children are a little more than what their age indicates. With anthelmintic the rule of age cannot be strictly adhered to, as the anthelmintic is not intended for absorption into the system, but for its action on the parasites.

Vomiting is the most serious symptom. It sometimes occurs after administering the saline purge and thus it might be caused in some cases by the latter. The incidence of vomiting increased with an increase of the dose administered. It is more frequent in children than in adults.

In delicate individuals carbon tetrachloride causes tenesmus, which may be severe. In cases with hæmorrhoids or severe rectal bilharziasis hæmorrhage may occur, which is alarming to the patient.

Contra-Indication to the use of Carbon Tetrachloride.

Carbon tetrachloride should not be given to cases suffering from evident renal disease.

It is better to avoid giving it to pregnant women till more information on the subject is available.

Cases with severe bilharziasis of the rectum with prolapse should not be given this drug, as well as cases with hæmorrhoids. Constipated individuals should be given a preliminary purge before administration of carbon tetrachloride. Repeated doses are more dangerous than a single large dose.

Inhibition of the Ova-laying Capacity of the Female Hook-worm after Administration of the Anthelmintic.

Following thymol and chenopodium treatment, it was observed that although the stools may be negative for a few days, re-examination after a longer interval gives a positive result. This has been ascribed to the inhibitory action of the drug upon the ova-laying capacity of the female worms left in the intestines. After an interval of ten to fifteen days the female worms begin laying their ova again. Unless this fact is taken into account re-examination during the inhibitory period gives a fallacious result.

It is thus important to find if a similar inhibitory period follows the administration of carbon tetrachloride. Amongst the 1,000 cases recorded in this report, there were 252 cases in whose stools ankylostoma ova were detected upon re-examination.

Aperient Action of Carbon Tetrachloride.

Carbon tetrachloride given without any purgative before or after administration causes looseness of the bowel. This is frequently accompanied with colic. The drug had a distinct aperient action. The number of ankylostoma worms voided was more when a purge was given. It is not clear, however, if the large number of worms expelled is due to a better action of the drug or to retarded elimination of the dead worms.

Carbon tetrachloride has this marked aperient effect in cases with loose stools, as it is indeed the case in most patients suffering from ankylostomiasis. When the drug is given to a constipated person unpleasant symptoms which are sometimes alarming are felt.

The following account is based on a personal experience in addition to two cases observed. In all these cases 5 c.c. of carbon tetrachloride were given with no purge following it. In my case the drug was taken as an experiment, no parasitic infection was present. The other two cases were infected with oxyuris only. The pungent taste of the drug is not very objectionable. It causes a sense of heat in the epigastrium.

Eructations sometimes follow the administration of the drug, causing the breath to smell of carbon tetrachloride. Colicky sensations are felt two or three hours after administration, and these increase in severity. Clammy sweats cover the body and

the extremities are cold. The patient is a little dizzy. If anything is taken by mouth it is vomited. An enema relieves the symptoms and the next morning the subjects feel well again. These symptoms occurred only in cases who were constipated at the time.

It is thus advisable to follow the administration of carbon tetrachloride with a purge as a routine measure.

Value of the Preliminary Purge.—A series of cases was given carbon tetrachloride on the basis of 5 c.c. for an adult, preceded and followed by a saline purge of magnesium sulphate. This was compared with another series in which the preliminary purge was not given. The patients after microscopical diagnosis were kept in hospital. In the evening 30 grammes of magnesium sulphate in water were administered to adult cases; children received the appropriate dose. On the following morning a dose of carbon tetrachloride in about 30 c.c. of water was given to each case, followed in three hours time by another dose of magnesium sulphate. Patients having no preliminary purge, took carbon tetrachloride four hours after the morning meal, i.e., practically on an empty stomach.

It is more advantageous to have a preliminary purge. On the other hand, a preliminary purge necessitates the admission of patients into hospital or at least deferring the treatment to another day. In a campaign or in using this treatment on a large scale this is a distinct disadvantage, as many of the cases will not turn up at the required time or will be unwilling to pass through this tedious process. Moreover, the patient is so weakened by the two consecutive purges as to be unable to work directly after the treatment.

Considering these factors as a whole, the preliminary purge is better omitted when using the drug on a large scale.

Result of Purge Given Before and After Varying Doses of Carbon Tetrachloride.—A trial was made with varying doses of carbon tetrachloride with a purge before and after it. The result was as follows: (1) One adult case was given 2·5 c.c. and was not cured. (2) Eight adult cases were given 4 c.c. each. The result was six cured and two uncured. The percentage of uncured was twenty-five. (3) Thirty-eight cases (adults and children) were given carbon tetrachloride on the basis of 5 c.c. as an adult dose. The percentage of cured was 89·5 and of uncured was 10·5. (4) Fifty-nine cases (all adults) were given 6 c.c. each, with the result that forty-five were cured and fourteen were uncured.

More cases are attacked with vomiting when taking the 6 c.c. dose, which probably accounts for the less favourable result. The conclusion that 5 c.c. adult doses with a saline purge before and after give the best result.

Carbon Tetrachloride followed by Castor-oil.—In this series no preliminary purge was given. Carbon tetrachloride 5 c.c. was administered four hours after the morning meal and followed in three hours by 30 c.c. of castor-oil in the case of adults and a corresponding dose in the case of children.

When any case was found to be still harbouring the ankylostoma worms on re-examination after the first treatment, a second treatment was given. If on re-examination the stools were still positive for ankylostoma ova the treatment was further repeated. Practically all the cases were given on the second and the third occasion a 5 c.c. dose and a saline purge following it whatever might have been the first treatment.

The conclusion is that by repeating the treatment of positive cases till a third treatment is administered, 98·6 per cent. of all the cases will be completely disinfested from the ankylostoma worms.

Most but not all the ankylostoma worms are passed during the first twenty-four hours following carbon tetrachloride treatment, while most of the ascaris are passed during the second twenty-four hours. More female ankylostoma worms than male worms are expelled.

COMPARATIVE RESULT OF TREATMENT BY CARBON TETRACHLORIDE, OLEUM CHENOPODII AND THYMOL.

All the cases were treated as out-patients. No preliminary purge was given, but the drug was followed in three hours by a purge. In the case of oleum chenopodii castor-oil was used; with the other two anthelmintics magnesium sulphate was used.

Dosage.—Oleum chenopodii was given in doses of 1·5 c.c. for an adult, 1 c.c. for children twelve to fourteen years, and ½ c.c. for children of seven years. The drug was given in gelatin capsules. Three courses of such treatment were given. Thymol was given two doses of 2 grammes for an adult, 1½ grammes for children twelve to fourteen years, and ½ gramme for children of eight years. The drug was given in cachets. Three courses of such treatment were given. Carbon tetrachloride was given in doses of 5 c.c. for adults. For children the doses were as stated in the previous table. One course of such treatment was given.

The result was as follows: of 737 patients treated with carbon tetrachloride 564 were cured; of 118 patients treated with oleum chenopodii 59 were cured; of 53 patients treated with thymol 20 were cured.

It is evident from this that carbon tetrachloride under the conditions detailed above is by far the best drug of the three and the cheapest to use.

EFFECT OF CARBON TETRACHLORIDE IN INTESTINAL PARASITIC INFECTIONS OTHER THAN ANKYLOSTOMIASIS.

Oxyuris Infection.—Large numbers of *Oxyuris vermicularis* worms are expelled as a result of the administration of carbon tetrachloride. In many cases several thousands of the parasites can be found when counting the ankylostoma worms expelled. The drug is more effective in this infection than any other known drug, but it does not afford a complete cure. Many cases after the lapse of three to four weeks are found to be infected in a mild degree. Oxyuris infection is one of the most difficult to cure.

Colonial Medical Reports.—No. 179.—Cairo (*continued.*)

Ascaris Infection.—Sixty-eight cases which harboured both ankylostoma and ascaris worms were given carbon tetrachloride on the basis of 5 c.c. adult dose followed by a purge of magnesium sulphate. The re-examintion showed that forty-nine were cured and nineteen were still harbouring the parasite. Carbon tetrachloride is inferior to oleum chenopodii as an anthelmintic in ascariasis.

Trichostrongylus Infection.—Seventeen cases harbouring this parasite in addition to ankylostomiasis were given carbon tetrachloride according to the above routine. Only one case was found on re-examination to be free from trichostrongylus infection.

Hymenolepis nana Infection.—Six cases harbouring *Hymenolepsis nana* were given carbon tetrachloride in 5 c.c. doses. None of them was cured.

Lamblia Infection.—Carbon tetrachloride was administered to three cases who had been suffering for a long time from dysentery characterized by irregular attacks with intervals of no complaints. Microscopical examination of the stools revealed the presence of *Lamblia intestinalis* only. The three cases were relieved of their dysentery infection after taking carbon tetrachloride, and examination of the stools was negative for *Lamblia intestinalis* and its cysts. Six months have passed since the treatment and the cases are enjoying good health. One of them, however, had dysenteric symptoms for one day, but these have disappeared without treatment. The stools were examined immediately after this attack, but no lamblia or cysts were discovered. So far the results of treatment of this resistant protozoal infection are encouraging.

SUMMARY.

Carbon tetrachloride is a valuable and safe anthelmintic in ankylostomiasis. It is effective to some extent in ascariasis and oxyuriasis. It is also a valuable remedy in lamblia infection.

The optimum dose for cases with *Ankylostoma duodenale* infection is 5 c.c. for an adult to be followed by a saline purge. The drug is more effective if preceded by a saline purge in addition. It is slightly aperient and is little absorbed in the intestine and is excreted in the stools.

No confinement to bed after administration is necessary.

Repeated doses of the drug are to be avoided except after a long interval.

The drug should not be given in cases with renal diseases; severe intestinal bilharziasis, hæmorrhoids, and hepatic disturbances.

Only pure carbon tetrachloride should be used; its freedom from poisonous impurities should be guarded against by previous administration to experimental animals.

Carbon tetrachloride is much cheaper than thymol or oleum chenopodii. It is particularly suitable for anti-ankylostomiasis campaigns.

III.—The Control of Bilharziasis in Egypt.

The Incidence of Infection.—Bilharziasis is a widely spread disease amongst the population of Egypt.

Although there is proof of the existence of bilharzia infection in mummies of 1250-1000 B.C., reliable records as to the incidence of infection in Egypt were collected during the latter half of the last century only.

The infection with bilharziasis is probably increasing in Egypt. This may be accounted for by the continuous construction of small irrigation canals and drains throughout the country. These are favourable places to the snail-carriers of bilharzia.

Infection with *Schistosoma hæmatobium* is probably homogeneous throughout the country, whilst infection with *Shistosoma mansoni* is practically localized to the north of the Delta. Other localities have still to be investigated before this conclusion can be accepted as final.

THE SCIENTIFIC BASIS OF MEANS OF CONTROL OF BILHARZIASIS.

Before the discovery of the life history of the schistosome parasites, the means of infection with the disease was not known and consequently prevention was merely guess work. It was suspected at an early period that water was the source of infection, but no serious efforts were attempted at prevention.

When the life history of the Egyptian human schistosome was discovered by Leiper, 1915-1918, it served as a sure basis for preventive measures.

Three species of genus *Bullinus* act as the intermediate hosts of *Schistosoma hæmatobium* (Bilharz, 1852); *Bullinus contortus* Michaud, 1829, *B. dybowsky* Fischer, 1891, and *B. innesi* Bourguignat.

The life cycle of *S. mansoni* Sambon, 1907, is similar to that of *S. hæmatobium*, substituting *Planorbis boissyi* Potiez and Michaud, 1388, for snails of the genus *Bullinus*.

If the life cycle could be broken at any of its stages, the parasites would not develop and the disease will be controlled. If the break in the cycle is a complete one the disease will be abolished, but if it is not thorough the incidence of infection will be decreased to a certain extent.

The possibilities of breaking the cycle can be discussed under the following headings: (*i*) Protection of man from being infected with the cercariæ; (*ii*) Guarding streams against pollution; (*iii*) Killing the miracidia; (*iv*) Extermination of the molluscan intermediary host.

Bilharziasis in Egypt is a problem of grave national importance. Statistics show that about 75 per cent. of the inhabitants are infected. The disease affecting children in early life arrests to a certain extent their bodily and mental development, whilst amongst adults it deteriorates the value of manual labour. It causes a good deal of suffering

and claims a big toll of mortality, which has been estimated by Griesinger at 25 per cent. of all deaths, and, according to Ferguson, at 8 per cent. In addition, it predisposes to infection with other diseases and diminishes the normal resisting power of the body.

The problem of combating this disease is both difficult and complicated, in addition to its enormous magnitude. The difficulties, however, are not unsurmountable.

A campaign proposed to combat this disease ought to be so planned as to attack the disease from different aspects at the same time. Each measure, although by itself might be inefficient, yet it will ensure to a certain extent the success of other measures. The following are the promising points of attack: (1) Prevention of the pollution of irrigation channels by (*a*) Erection of house and village latrines and inducing the inhabitants to use them; (*b*) Propaganda amongst inhabitants illustrating the dangers of stream pollution (*c*) If possible enlisting the co-operation of religious authorities in condemning stream pollution.

(2) Guarding water used for drinking and household use by: (*a*) Localizing the spots where villages can draw their water. These must be from the river or canal where no snails are present; (*b*) Protecting that locality from pollution; (*c*) Advising the inhabitants to store their water on the premises for forty-eight hours before use.

(3) Attempt at exterminating the mollusca by: (*a*) Utilizing the summer rotation of irrigation in Egypt causing dryness of the small irrigation channels; (*b*) Treating the small amount of water left in these channels with copper sulphate solution; (*c*) Guarding the intake of these channels against the introduction of snails by proper sieves if possible.

(4) Treatment of infected individuals on a large scale.

At present the attempt at the extermination of snails appears the most promising. The system of irrigation in Egypt controls in a unique manner the water supplied to any particular area. The co-operation of the Irrigation Department with the Department of Public Health in such a project is fundamental.

IV.—Parasitic Diseases at Saft el Enab Village.

Intestinal and Urinary Parasitic Worm Infection in an Egyptian Village.

The investigations detailed in this report were carried out at Saft el Enab, a village near Damanhûr, in the Delta. There was an unexplained high incidence of mortality in the village during 1922. The opportunity of investigations being undertaken at the village was utilized to arrive at the extent of parasitic worm infection in a fair sample of the population. This included representatives of all age periods of both sexes, as well as the different social classes met with in such a village.

Four registered midwives were employed in visiting houses and collecting samples from women. It was evident that only the poor women who were mostly field workers submitted specimens easily. The midwives could not influence women from better class families to do the same.

With males, conditions were different. They were easily influenced by argument and demonstration of the different phases of the life history of some parasites and the havoc brought about by them. Microscopical demonstration of living specimens always appealed to them. In spite of their lack of education, these people were very sensible and inquisitive, discussing what they see when they are treated in a gentle manner.

Method of Examination.— Urine was centrifugalized and the deposit was pipetted into a watch glass and examined with a low power of the microscope for *S. hæmatobium* eggs. It was found that sedimentation in a conical urine glass and examining the sediment was not sufficiently accurate to show cases of mild infection.

A smear of the fæces on a slide 3 × 1 inches was examined. In addition about 1 gr. of the stool was emulsified, strained in a wire sieve and concentrated sodium chloride solution added to it (floatation method). After fifteen to twenty minutes the surface film was lifted by means of a platinum loop and examined for eggs.

In most cases the hæmoglobin index was tested by the Talquist hæmoglobinometer; blood-films were made for differential counts and the weight and height of the person were recorded as index to his state of nutrition.

Treatment was administered to those who voluntarily applied for it, which, after a few demonstrations of *Ascaris* and *Tænia saginata* expelled, included most of those examined.

Of the 274 persons whose urine and fæces were examined, 262 were found to be infected with one or more parasites, and only twelve individuals were free from any evidence of infection as could be detected by the methods employed. This gives an incidence of parasitic worm infection in the whole population of at least 95·6 per cent., and only 4·4 per cent. of the population are presumably free.

Species met with.—Ova of nine species of helminth parasites and the larvæ of one were met with during the investigation. These were:

Trematodes.—(1) *Schistosoma hæmatobium* (Bilharz, 1852) Weinland, 1858. (2) *S. mansoni* (Sambon, 1907) Leiper, 1918.

Cestodes.—(3) *Tænia saginata*, Goez, 1782. (4) *Hymenolepis nana*, von Siebold, 1852.

Nematodes. —(5) *Ascaris lumbricoides*, Linnæus, 1758. (6) *Ankylostoma duodenale* (Dubini, 1843) Creplin, 1854. (7) *Strongyloides stercoralis* (Bavay, 1876) Stiles and Hassal, 1902. (8) *Trichocephalus trichiurus* (Linnæus, 1771) R. Blanchard, 1895. (9) *Eterobius vermicularis* (Linnæus, 1758) Leach, 1853. (10) *Trichostrongylus sp.*

Bilharzia Infection.

Snails in the Irrigation Canals.

The canals were all surveyed for their molluscan fauna. The following species were found: 1—*Bullinus contortus*, Michaud, 1928. 2—*B. dybowski*, Fischer, 1891. 3—*B.* (*Pyrgophysa*) *forskali*, Ehrenberg, 1831. 4—*Cleopatra bulimoides*, Olivier, 1804. 5—*Lanistes bolteni*, Chemnitz, 1786. 6—*Planorbis boissyi*, Potiez and Michaud, 1838. 7—*P. mareoticus*, Innes, 1884. 8—*Vivipara unicolor*, Olivier, 1801.

Of these species, Nos. 1 and 2 interest us as carriers of *Schistosoma hæmatobium*, and Nos. 6 and 7 as carriers of *S. mansoni*. The species of *Planorbis* were fairly common all along the terminal branches of the irrigation canals. Where these canals have been cleaned lately the shells were quite evident in the dry mud on either side of the channel, attracting attention by their white colour. *P. boissyi* was by far the commonest species met with.

Only eight specimens of *P. mareoticus* were collected. *Bullinus* was fairly common in these canals, although in less numbers than *Planorbis*.

S. hæmatobium infection was more widespread than infection with *S. mansoni*.

All classes of the community and both sexes were infected with *S. hæmatobium* to practically the same extent. The infection was very mild. None complained of the disease. They had very mild bladder symptoms which they did not trouble about. On the other hand, the field workers were heavily infected with *S. mansoni* and were in many cases incapacitated by it. The universal complaint was diarrhœa with blood. Some of the children and females who occasionally visit the fields and do some work there, were infected in a mild degree with *S. mansoni*, but they seldom complained of any symptoms, the ova found in the stool being in most cases the only clue to their infection.

Schistosoma hæmatobium.

Infection with this parasite is by far the most prevalent at Saft el Enab. No less than 73 per cent. of the 318 individuals whose urine was examined were found to be infected. The infection was common in all classes of the community and in both sexes. Specimens of urine were centrifugalized, if direct examination of the deposit proved negative to *S. hæmatobium* ova. High speed centrifugalization destroys the ova and liberates the miracidia. 300-400 revolutions per minute for one or two minutes is all that is required.

In most of the 232 positive cases of *S. hæmatobium* infection, the characteristic ova were met with in the urine.

When tartar emetic is administered to cases with both *S. hæmatobium* and *mansoni infection*, the ova disappear from the urine long before any change could be noticed on *S. mansoni* ova in the stools.

In no case was *S. mansoni* ova met with in the urine.

Schistosoma mansoni.

Infection with *S. mansoni* is limited to the intestinal tract, particularly to the large intestine.

The ova of this parasite are detected in smear preparations of the stools mixed with normal saline or water and examined with a low power of the microscope.

The floatation method devised for detecting *Ankylostoma* ova destroys the ova of *S. mansoni* owing to the high osmotic pressure of the solution causing the ova of the latter parasite to collapse and thus rupture.

The ova of parasites living in the small intestine, i.e., *Ankylostoma*, *Ascaris*, &c., are thoroughly mixed with the liquid contents of the bowel and can be looked for with safety in any portion of the stool.

The condition is different from *S. mansoni*, the ova are voided through the mucus membrane of the large intestine, particularly that of the sigmoid and rectum. The fæcal contents of the sigmoid portion of the gut under normal conditions are solid or semi-solid in consistence. The rectum under normal conditions is empty.

The ova are found smeared on the surface of the fæces in a layer of mucous that surrounds the fæcal mass and particularly in the last portion of the stool mixed with blood and mucus if present.

In cases where there is diarrhœa the eggs are mixed with the motion to a certain extent. In such cases if blood is present, it is in the portion containing it that most of the ova are found.

It is extremely important where *S. mansoni* infection is suspected to have the whole of the stool sent for examination and the proper portion selected for making the smears. Instructing the patient to bring a piece of the stool in a small glass tube will certainly lead to negative findings where proper examination would have revealed infection with this parasite.

In view of the difficulty in finding *S. mansoni* ova in the stool, especially when one smear is examined, it is almost certain that the reported incidence with this parasite underestimates the true condition of affairs. *S. hæmatobium* infection of the urinary tract is easily detected, and thus the reported results probably reveal the actual condition as regards the prevalence of that infection.

Tænia saginata.

Ova or segments of *Tænia saginata* were met with in the fæces of three individuals only. They were all males. It is interesting to note that two were brothers and both were butchers by trade. On inquiry as to ingestion of uncooked meat it was revealed that both brothers used to eat a little of the raw peri-nephritic fat so as to entice the customers as to the good quality of their meat.

Four c.c. of *Filix mas* extract were administered after a preliminary twenty-four hours' fasting and a saline purge. Another purge followed three hours later. The older brother (24 years old) passed one

T. saginata coiled in one lump complete with head and very few detached mature segments. The whole worm measured 425 cm. when it was in a fresh condition. The younger brother (18 years old) passed two *T. saginata* worms. They came out in a long string and took more than two hours in passing. It was a very tedious process. In spite of instructions not to pull them out, forcible traction was evidently used, with the result that the string of strobila was broken. Neither head was found, although pieces measuring more than 2 metres of both worms were passed comprising the very small immature segments 1-2 cm. from the neck region. These unmistakably belonged to two different worms.

The older brother harboured in addition *S. hæmatobium* and *mansoni*. His hæmoglobin index was 85 per cent. The younger brother harboured *S. hæmatobium* and *Ascaris* in addition to the *T. saginata*.

The third case was a carpenter 28 years old. There was no history of his eating raw meat. He harboured in addition *S. hæmatobium* and *Ascaris*.

It is to be expected that *T. saginata* infection will be found to be comparatively common in Egyptian villages. The meat is not inspected and thus there is no means of condemning infected carcases before consumption.

Hymenolepis nana.

This parasite of man is identical morphologically with *Hymenolepis fraterna*, a cestode which is a common parasite of rats and mice. It is, however, distinct from it biologically, each species being peculiar to its host only.

There is a good deal of evidence to show that the ova of this parasite are seldom recognized by practitioners in Egypt, and so it has so far attracted little or no attraction.

Fives cases of *Hymenolepis* infection were met with. Three were males under ten years of age and two were females both between twenty and thirty years old.

It was not possible to treat these cases and secure specimens of the parasite and study their pathogenic effect on the host.

The eggs, which were quite distinctive, float in concentrated saline solutions and thus could be detected by the floatation method.

Very little is known about the pathogenic action of *Hymenolepis* infection. Nervous symptoms and derangement of digestion are ascribed to it. It is commonly a parasite of children, although it is sometimes found in adults.

Ascaris lumbricoides.

Next to *Schistosoma hæmatobium*, *Ascariasis* is the most widespread parasitic infection met with at Saft el Enab. No less than 64 per cent. of the inhabitants showed evidence of its presence. In most of the 210 positive cases the ordinary fertilized ova of *Ascaris* were seen. In seven cases, however, unfertilized ova only were found. These are irregular in shape, rather elongated and bear the characteristic knobs seen on the normal eggs, which are frequently stained yellow or brown with bile.

Unfertilized eggs signify the absence of male worms from the intestine. This is frequently the case when the host harbours a single worm or at most two. Two of the seven cases showing unfertilized eggs were treated with santonin. One passed a single female and the other passed two females.

It is peculiar that infection with a single *Ascaris* is frequently accompanied with serious nervous symptoms, especially in children and young adults.

In one case both fertilized and unfertilized *Ascaris* eggs were seen. Such a coincidence could not be easily explained unless we suppose that one female got isolated from the rest of males. Whatever may be the right explanation the fact is worth recording.

Ova of *Ascaris* were sometimes met with having a smooth outline and no bosses on the surface. The ovum is easily mistaken by the uninitiated for that of *Ankylostoma duodenale*. Its thick shell and unsegmented content ought to be sufficient to indicate its true nature.

Judging from the approximate number of ova met with in one slide the infection was found to be severest amongst children. In one case a male child of seven years expelled as a result of treatment with one dose (0·20 gm. santonin) 81 *Ascaris* and he was still passing worms. The number of worms passed by this child caused an excitement amongst the inhabitants, who applied for examination in large numbers as a result of this practical demonstration.

Ankylostoma duodenale.

Amongst 331 individuals examined, evidence of *Ankylostoma* infection was found in 55 cases.

In all cases a smear was first examined and then the floatation method was applied. The latter method was very successful, especially as the *Ankylostoma* infection in most cases was very mild and few eggs only could be seen. It was found necessary to leave specimens in salt solution for fifteen to twenty minutes before examining the surface. Otherwise, the results could not be relied upon.

Clinically severe cases of ankylostomiasis were very rarely met with.

The following method for examination for *Ankylostoma* larvæ was found to be the most effective. About 40 gm. of fæces are taken and mixed with 2 c.c. of water to form a thin paste in the bottom of a large Petri dish 17 cm. in diameter. The cover of the Petri dish is lined with a circular disc of filter paper which is always kept moist. It is found necessary to moisten that filter paper once every twenty-four hours. The preparation is always kept closed. In Egypt it is sufficient to keep the Petri dishes at room temperature. In colder climates it it best to keep it in an incubator at temperature ranging from 25° C. to 30° C.

Colonial Medical Reports.—No. 179.—Cairo (*continued*)

It is found that the mature larvæ migrate from the fæcal mass upwards to the moist filter paper in the cover. They can be collected by swelling the cover with a few c.c. of warm water and pouring it into a proper receptacle when it is found to contain the larvæ free from the fæcal matter.

The process of collecting larvæ can be repeated every day for several days. From one such preparation as much as 40,000 larvæ were collected in four days.

It was found that success depends upon the reaction of the medium, the slightest acidity continuing over several days kills the larvæ. Excess of alkalinity has the same effect. The best medium is neutral or slightly alkaline.

In cultures kept at room temperature ranging from 33° C. to 37° C. mature larvæ were collected on the third day. Details of observations on the development of larvæ will be published later.

Enterobius vermicularis.

The eggs of this parasite were met with in the stools of five cases only. This does not give any idea as to the real incidence of infection with this parasite. The eggs are seen in the stools only in rare circumstances when the adult female is ruptured, due to injury or manipulation of the specimen.

In connection with another investigation at Qualyûb, *Enterobius vermicularis* eggs were seldom seen in the stools, but on administration of anthelmintics for *Ankylostoma*, adult *E. vermicularis* were met with in a high percentage of the cases.

It is probable that the infection is widespread, although it cannot be gauged by the examination of the stools for eggs. That the presence of eggs in the stools is in most cases the result of rupture of the adult females is confirmed by the common experience that eggs, whenever met with are found in large numbers.

Trichostrongylus sp.

The egg of *Trichostrongylus* as seen in the fresh stool has a thin transparent shell and contains a morula. It is rather longer and narrower than the *Ankylostoma* egg, for which it is commonly mistaken. This egg was met with in eight cases. It is easily detected by the flotation method as applied to *Ankylostoma*. There are three species of *Trichostrongylus* that are reported from man in Egypt. All three species inhabit also the intestine of sheep and camels in Egypt.

These species are: (1) *Trichostrongylus instabilis* (Railliet, 1893), Looss, 1895. (2) *T. probolurus* (Railliet, 1896), Looss, 1905. (3) *T. vitrinus*, Looss, 1905.

It is practically impossible to distinguish between these various species from the ova which are closely identical. It is only by adult specimens that the species can be determined. The pathogenesis of these parasites is not known.

Intestinal Bilharziasis causing an Epidemic-like Increase of Mortality in an Egyptian Village.

History of Outbreak.

Towards the end of August, 1922, the Medical Officer of Markaz Kôm Hamâda noticed that for some time past there was a steady increase in the number of deaths at Saft el Enab.

A cordon was established at the village on August 26, and all sick people were compulsorily isolated. From the beginning there was no uniformity in the symptoms or signs manifested by the patients. The medical officers in touch with the cases were not in agreement as to the cause of the outbreak or as to the diagnosis of the malady.

Mixed bacillary dysentery was the diagnosis tentatively arrived at. Antidysenteric serum was given a trial, but its results were unfavourable. Better results followed the use of emetine, which was tried empirically, although amœbæ or cysts were not found in the stools of patients to any extent.

We are in a position now to understand why emetine gave better results. It benefited the bilharzia, which was the main cause. In addition, as the disease ended in some cases fatally there was an opportunity for a careful post-mortem to be carried out.

The number of cases received at the hospital was twelve, of whom five died. None of these cases had any rise of temperature in hospital except for an occasional day following intravenous injection of tartar emetic. All of them were emaciated and weak although not confined to bed. They had suffered from diarrhœa with blood for a long time in the past with periods of improvement and subsequent relapses. Many of these cases lost one or more adult male relatives by the same disease. Their women relatives were healthy.

The freedom of women and children from this disease was one of the most interesting and peculiar features of the outbreak. On instructing the midwives to collect specimens of urine and fæces from women in the village, we were told with evident chagrin that the women were flourishing and healthy and it was only the poor men who were affected.

One thing was common in the post-mortem findings of all cases examined and that was bilharziasis of the intestine in varying degrees of severity. It was frequently associated with peripotal cirrhosis of the liver.

It is evident from the clinical, laboratory and post-mortem findings that the majority of the cases seen at Saft el Enab were suffering from severe bilharziasis of the intestinal tract. The severity of the infection can be gleaned from the fact that *Schistosoma mansoni* ova often in large numbers were easily demonstrated in the small amount of fæces sent on cotton swabs for bacteriological examination. Nine out of twelve swabs were found to contain ova.

Although clinical and post-mortem examination pointed to intestinal bilharziasis as the main cause of the disease and mortality at Saft el Enab, the outbreak was labelled bacillary dysentery. Bilharzia is so common in Egypt that it is held in contempt by the medical profession. It is not thought to be a sufficient cause for death. This is borne out by the numbers of death returns labelled as due to bilharziasis or ankylostomiasis in the whole country.

Intestinal bilharziasis in fairly advanced condition is a serious disease. With the large intestine studded with large fleshy papillomata that are liable to slough and leave ulceration, the raw surfaces are constantly irritated by the faecal contents of the bowel and exposed to their multifarious bacterial contents. They are occasionally parasitized by the *Entamœba histolytica* of dysentery. Cirrhosis of the liver (periportal type) is frequently present in advanced cases.

The inevitable diarrhœa caused by irritation of the bowel is chronic, lasting for months. This is generally accompanied by a certain degree of toxæmia having in most cases a fatal termination. The cause of death is labelled in many cases dysentery, heart failure, cirrhosis, &c., and the primary cause is not mentioned.

Why the disease assumed an epidemic-like course at Saft el Enab is not definitely known, but two theories are offered: (*a*) A super-imposed heavy infection with intestinal bilharziasis occurred during the summer of 1922. The channels around Saft el Enab are a suitable habitat for the snails; or (*b*) A mild bacterial infection broke out, i.e., bacillary dysentery to which the adult males previously debilitated by bilharziasis succumbed while the other members of the community escaped. The series of end canals surrounding Saft el Enab sufficiently explained the high incidence and severity of intestinal bilharzial infection.

The main feature of the outbreak at Saft el Enab is the excessive mortality of adult males. Similar conditions have been prevailing at this and other villages during the previous years. The only difference was that these deaths were spread throughout the year and thus had attracted no attention. In some villages the number of deaths in adults was as much as five times the expected number of deaths.

Recommendations carried out at Saft el Enab.

At the time during which the investigations were carried out the following routine was gradually evolved: (1) Tartar emetic to be administered intravenously to all cases of bilharzial infection. (2) Ankylostomiasis cases were treated with thymol, and ascariasis and santonin. (3) Segregation of the sick was stopped. All patients were allowed to proceed to their houses.

They were instructed to visit the cordon at the proper time for treatment. (4) All debilitated individuals were given free meals at the cordon three times a day. The following proposals were submitted to the Irrigation Authorities with a view to modifying the course of the canals round Saft el Enab to make them less suitable as a habitat for the snails. (1) The canal passing through the village to be abolished. (2) Reconstruction of the irrigation canals to ensure a continuously flowing water with no dead ends. (3) To establish such a canal at a considerable distance from the village buildings, to lessen the chance of young children becoming infected and to the people from using it for the disposal of refuse. (4) Encouraging the people to use "sakias" (water wheel) instead of the universal use of the "tambour."

(5) The extension of Kalashan drain which ends within two kilometres from the village so that it may help in draining the surrounding marshes. It will also be useful in another way. During "taharik" when most canals are dry, the canals at Saft el Enab contain a certain amount of water which preserves the life of the snails. A drain in the locality will help in drying up these canals and thus destroying their snail inhabitants.

Bilharziasis of the urinary tract is widely spread amongst the inhabitants of Nag Hamadi district. About 75 per cent. of the total inhabitants are infected. Ankylostomiasis infection is present to a lesser extent. About 44 per cent. of the inhabitants are infected.

The widespread bilharzia infection is significant as it has been stated by authorities that bilharzia infection is not widespread in Upper Egypt. This was thought to be principally due to the absence of irrigation schemes which necessitate the presence of canals and drains, which are the principal habitat of the snail carriers of bilharzia.

Such irrigation channels are found around Nag Hamadi district.

Most of these canals are the result of private enterprise on the part of His Highness Prince Youssef Kamal and a European company established in the neighbourhood. It might be safely concluded that these irrigation schemes caused the spread of bilharzia infection amongst the epople.

It is in the interest of those large proprietors that the inhabitants of Nag Hamadi district should be freed of their infection as they would become better fitted to carry on the agricultural work for the landowners. At present most of the agricultural class are depleted by this chronic disease, which is often contracted during childhood, of a good share of their energy. The landowners are obliged to employ them weak as they are at the standard market value.

VI.—A New Trematode Parasite of the Rat, Echinostoma Ægyptiaca nov. sp.

During the summer of 1923 a rat, *R. rattus*, was caught in the Public Health Laboratories, Cairo. The animal was killed and dissected for evidence of parasitic infection. Blood-films contained *Trypanosoma lewisi* in large numbers. In the small intestine seven *Trematode* parasites were found.

The *Trematodes* were living and the microscopic examination revealed that they were members of

the family Echinostomidæ. All the parasites were adults with the uterus full of ova. The ova were detected in the fæces of the animal.

Hitherto only one species of this family, *Echinostoma spiculator*, was described from the rat by Dujardin in 1845. We are indebted to Professor R. T. Leiper, of the London School of Tropical Medicine for supplying us with the account given by Dujardin on *E. spiculator*. On careful study of the scanty literature available of this parasite we came to the conclusion that the *Echinostoma* met with in Cairo is specifically different from Dujardin's species. We propose to name it *E. egyptica*.

Description of the Parasites.

Fresh specimens are pinkish in colour. Specimens fixed in Schaudinn are dirty white. Preserved specimens are about 6·6 mm. in length and 0·8 mm. in breadth. Fresh specimens vary in length according to their condition of contraction or relaxation. The parasite is elongated, ribbon-like with a tapering cephalic end and a rounded caudal extremity. The cephalic end is triangular in shape, its apex contains the oral sucker with the mouth opening. The body is flattened dorso-ventrally.

The cephalic extremity is surrounded by a double row of 43 thick pointed spines. The cephalic third of the body is closely beset with small spines over the whole surface. Caudal to the ventral sucker, the cuticular spines become fewer and far between, caudal to the testes they apparently cease altogether. The cephalic pole is triangular in shape and is separated from the rest of the body by a distinct groove. It is surrounded peripherally by a double row of spines, which encircles the head except at the middle line ventrally. They are forty-three in number. On either side of the middle line ventrally there is a group of five spines, i.e., close to one another. Each spine is 50 microns in length. The spines are crowded laterally but are wider apart dorsally. The ventral sucker is placed in the mid-ventral line closer to the cephalic line than to the caudal end. It is one millimetre distant from the cephalic extremity. The sucker is large in comparison with the size of the *Echinostoma*. It is 0·5 millimetre in diameter. The oral aperture opens at the pointed cephalic end. It is 0·10 millimetre in length, being little longer than it is broad. The opening leads into a thin elongated œsophagus surrounded with a thick globular muscular bulb. The intestinal cæca branch from the œsophagus 0·7 millimetre from the cephalic extremity. The intestinal cæca are thin and curving round the acetabulum, pursue a direct course caudally till they end blindly close to one another at the posterior end. Each intestinal cæcum is a little shorter than the length of the parasite and lies close and parallel to the lateral border of the worm. The cæca are hidden from view in most of their course by the profuse vitelline glands.

All the genital organs with the exception of the vitelline glands lie between the two testinal cæca.

Male Organs.—The two large testes lie caudad of the ovary one cephalad of the other, close to the caudal end of the worm. The caudal testis lies 1·5 millimetres from the posterior end. Each testis is elongated and slightly lobed. The anterior testis is 0·78 millimetre in length and 0·46 millimetre in breadth. The posterior testis is 0·9 millimetre in length and 0·37 millimetre in breadth. The space between the testis is 7 microns. The cause of the vast difference could not be traced. The cirrus sac is large and elongated, being 0·5 millimetre in length. It opens into the genital pore close to the bifurcation of the intestinal cæca cephalad of the acetabulum.

Female Organs.—The ovary lies in the mid-ventral line practically midway between the cephalic and caudal ends. It is pre-testicular. The ovary is rounded in shape, being 0·3 millimetre in diameter and 0·3 millimetre cephalad of the anterior testis. The fine ovarian duct begins at its caudal extremity and is surrounded by the large and irregularly shaped shell gland which lies close to the ovary. To the right of the shell gland lies the large receptaculum seminis while caudal to it, the two vitelline ducts meet and join the ovarian duct.

The vitelline glands are numerous and extend over more than two-thirds of the total length of the body surrounding and obscuring from view the intestinal cæca. The glands on either side approach caudad of the posterior testis extending as far as the mid-ventral line.

The uterus is slightly convoluted and lies mostly in the mid-ventral plane between the two intestinal cæca cephalad of the ovary. It is packed with ova. The termination of the uterine canal passes dorsal of the acetabulum ending in the vagina which opens into the common genital pore in conjunction with the male organs.

Ova.—The ova are deep brown in colour and oval in shape. They are operculated. The ovum is 100 microns in length and 57 microns in breadth. Ova contain collections of cells with a large amount of yolk. The genital opening lies in the mid-ventral line anterior to the acetabulum and posterior to the junction of the intestinal cæca. The genital opening is not raised above the surface of the body.

Excretory Organs.—The excretory pore lies at the caudal extremity. The excretory vesicle is hidden by the vitelline glands.

Host.—The common house rat (*R. rattus*).

Habitat.—Small intestine.

Locality.—Cairo, Egypt.—The type species has been deposited in the Parasitological Museum of the Public Health Laboratories, Cairo.

VII.—Complement Fixation Reaction in Bilharziasis by the use of Fasciola Hepatica Extract as an Antigen.

The present investigation was undertaken before the writer was aware that some serologists in Europe have already attempted the serum diagnosis of bilharziasis by using *Fasciola hepatica* extract as an antigen.

The idea was that as liver fluke infection and bilharziasis were two diseases caused by two parasites of the same class, a serological group reaction might be present, similar to that found in bacterial infections.

Fairley's complement fixation for bilharziasis requires an antigen prepared from cercaria infected snail livers. Such material is not always available and cannot moreover be easily prepared. Liver flukes, on the other hand, are met with in every slaughter-house and exist in such large quantities to allow of easy preparation.

Hoppli appears to be the first to have recorded results showing that he obtained positive complement fixation in infections of both *Schistosoma mansoni* and *S. boris*. He employed alcoholic extracts of adult *F. hepatica* as an antigen.

Bettencourt and Borges, repeating Hoppli's experiments, were unable to confirm his results with cases of *S. hæmatobium*. Out of twenty-three bilharzia cases, seventeen gave negative results and six only were positive.

Le Bas found that alcoholic extracts of *F. hepatica* were capable of fixing complement in a greater degree with sera from persons infected with *Schistosoma* than with normal sera. The fixation with the sera investigated was found to be weak and of little diagnostic value.

Recently Fairley and Williams showed, in corroboration with other former co-workers, that in hepatica distosomiasis of sheep, specific antibodies were present in the blood of the infected animals, and that extracts of *F. hepatica* possess true antigenic properties. The authors recommend the complement fixation test for the diagnosis of fluke infection in man.

Preparation of the Antigen.

(1) *Alcoholic Extract.*—Fresh flukes obtained from the bile ducts of infected sheep were thoroughly washed with normal saline solution to get rid of the bile. 20 grm. of the washed flukes were well ground with sand in a mortar. 200 c.c. of alcohol (95 per cent.) were added to the resulting paste, and the whole was put in a sterile bottle. The bottle was left for seven days in the incubator at 37° C., being well shaken daily. The extract was then filtered through filter paper.

(2) *Watery Extract.*—This extract was prepared in the same way as the previous one, with the exception that half per cent. carbolic saline was used instead of alcohol, and the incubation was for twenty-four hours only.

The antigens were then standardized for the estimation of their anti-complementary dose. One-third of this dose was taken as an antigen dose for the complement fixation test.

Technique of the Complement Fixation Test.

0·5 c.c. of a 1 : 4 dilution of the patient's serum, 0·5 c.c. of antigen and 0·5 c.c. of fresh serum of guinea-pig (diluted 1 : 10) were placed in a water bath at 37° C. for 40 minutes. To this, 0·5 c.c. of a 5 per cent. emulsion of sheep's red blood-corpuscles and 0·5 c.c. amboceptor (4 m.h.d.) were added. After remaining for 20 minutes in the water bath, the result was read.

The investigations here recorded were made on 79 cases of *Bilharzia hæmatobium* infection in which ova were present in the urine, and on 32 negative cases in which no ova were found. The alcoholic extract was used in 45 of the positive cases and in 20 of the negative cases.

The carbolic saline extract was used in 34 of the positive cases and in 12 of the negative cases.

The Wassermann reaction was done with all sera, using the alcoholic extract. Cases showing positive Wassermann reaction were eliminated.

The results of complement fixation in bilharziasis cases using the alcoholic extract show that the alcoholic fluke extract is capable of binding complement with 71·1 per cent. of the positive bilharziasis sera.

With carbolic saline extract, fixation occurred in 67·6 per cent.

Some of the negative cases gave also complement fixation with fluke extracts. This may be explained by the fact that these cases were not after all negative. Microscopical examination alone of the urine does not eliminate the possibility of bilharzia infection in a country like Egypt where the disease is widespread.

In addition, intestinal bilharziasis, which is also fairly common in Egypt, has not been excluded in the negative cases here cited.

Conclusion.

Alcoholic and watery extracts of *F. hepatica* possess antigenic properties against sera of bilharziasis cases, which can be demonstrated by the complement fixation test.

The diagnostic value of the test is limited, as practically 30 per cent. of the positive cases gave negative results.

F. hepatica extracts cannot be utilized for the diagnosis of *F. hepatica* infection in a man in countries where bilharzia is endemic.

VIII.—The Classification of the Family Ankylostominæ.

The classification of the Ankylostominæ has been the subject of discussion among helminthologists for a long time. Lane, in 1917, reviewed the subject and proposed to amend the definition of the subfamily Ankylostominæ, limiting it to the genus *Ankylostoma* only. This would appear to be justifiable, but he also proposed a new subfamily Necatorinæ synonymous with Bunostominæ, Looss, 1911, with certain amendations.

The reasons given by Lane for proposing a new subfamily were:

(1) The possibility that the genus *Bunostomum*, Rail., 1902, may be a synonym of *Monodontus*, Molin, 1681. Railliet and Henry had, however, disposed of this in 1910 in a paper entitled "Quelques helminthes nouveaux" in which they defined the genus *Bunostomum* and proposed the name *Eumonodontus* for *Monodontus* and defined it. The name *Eumonodontus* is now merely a synonym.

Colonial Medical Reports.—No. 179.—Cairo (*continued.*)

(2) Lane preferred to have the type of the family the genus *Necator*, which was more familiar than *Bunostomum*. This does not justify discarding a previously established family name.

Leiper, 1908, was the first to divide the bursate nematodes with a mouth capsule into: (*a*) those with a mouth guarded by a corona radiata—"Strongylinæ," and (*b*) those with dilated mouth capsule guarded by teeth or cutting plates and curved dorsally—Ankylostominæ. This is a classification based on very natural and outstanding characteristics.

Railliet and Henry, 1909, classified all bursate nematodes with a mouth capsule under the Ankylostominæ. Looss, 1911, raised the subfamily Ankylostominæ, Leiper, 1908, into a family rank Ankylostomidiæ. He restricted the subfamily Ankylostominæ to *Ankylostoma* and *Uncinaria*. The genus *Uncinaria* is certainly more allied to *Bunostomum* and *Necator* than to *Ankylostoma*. This is the view held by Lane, 1917, who restricted the subfamily to the genus *Ankylostoma* only.

The classification proposed by Hall, suppressing the family Ankylostomidæ, is a retrograde step on what had been advanced before.

The following scheme agrees in essential detail with Lane's classification with the single exception of re-establishing the subfamily Bunostominæ in an amended form.

FAMILY ANKYLOSTOMIDÆ, LOOSS, 1911.

Definition.—Bursate nematodese, with a horny mouth-capsule with its aperture pointing dorsally. No corona radiata. The family contains so far two subfamilies:

1.—Ankylostominæ, Leiper, 1908, amended Lane, 1917. Opening of mouth capsule is provided ventrally with paired chitinous teeth, vulva in the posterior part of the body. Type genus: *Ankylostoma*, Dubini, 1843. Type species: *A. duodenale*, Dubini, 1843. Other genera: *Galoncus*, Railliet and Henry, 1918. Type species: *G. perniciosus*, von Linstow, 1885.

KEY TO GENERA OF ANKYLOSTOMINÆ.

Mouth capsule greatly reduced in size and is provided with a dorsal cone and two dorsal lancets; inhabits cysts in the intestinal cell—*Galoncus*.

Mouth capsule was reduced in size; opening of dorsal œsophageal gland does not project freely into the mouth cavity, inhabits the lumen of the intestine—*Ankylostoma*.

2.—Bunostominæ, Looss, 1911, amended.

Opening of mouth capsule is provided with smooth chitinous plates, vulva about the middle of the body. Type genus: *Bunostomum*, Railliet, 1902. T. S. *Trigonocephalum* (Rud., 1908), Railliet, 1902.

Other genera: *Bustomum*, Lane, 1917. T. S.: *B. phlebotomum*, Raill., 1900. *Necator*, Stiles, 1903. T.S.: *N. americanus*, Stiles, 1902. *Brachyclonus*, Raill. and Henry, 1910. T.S.: *B. indicus*, R. and H., 1910. *Gaigeria*, R. and H., 1910. T.S.: *G. pachyscelis*, R. and H., 1910. *Bathmostomum*, R. and H., 1909. T.S.: *B. sangeri*, Cobbold, 1879. *Grammocephalus*, R. and H., 1910. T.S.: *G. clathratus*, Baird, 1868. *Monodontus*, Molin, 1861. T.S. *M. semicircularis*, Molin, 1861. *Uncinaria* (Froelich, 1789), Looss, 1905. T.S.: *U. criniformis* (Goeze, 1782), Raill., 1899.

KEY TO THE GENERA OF BUNOSTOMINÆ.

1.—Intestine with a diverticulum running towards head end. Teeth springing from floor of mouth with tips notched—*Grammocephalus*.

Intestine simple: 2.—Buccal capsule with shelf-like projections. Externo-dorsal ray arises from the corresponding branch of dorsal ray—*Bathmostomum*.

3.—Dorsal and externo-dorsal rays asymmetrical: Two ventral lancets in floor of mouth—*Bunostomum*. Two ventral and two dorsal lancets present—*Bustomum*.

4.—Bursa, pincer-like, dorsal lobe well developed; mouth with two ventral lancets only: Dorsal ray tridigitate; vulva in anterior half of body—*Gaigeria*. Dorsal ray bidigitate; vulva in posterior half of body—*Monodontus*.

5.—Buccal capsule with four lancets in relation to the dorsal cone: Externo-dorsal ray narrowed at its origin; spicules barbed at their tip—*Necator*. Externo-dorsal ray not narrowed at its origin; spicules not barbed—*Brachyclonus*. Buccal capsule with two ventral lancets only in relation to dorsal cone—*Uncinaria*.

Colonial Medical Reports.—No. 180.—Bihar and Orissa.

ANNUAL REPORT OF HOSPITALS AND DISPENSARIES IN BIHAR AND ORISSA FOR THE YEAR 1923.

By COLONEL H. AINSWORTH, M.B., F.R.C.S., I.M.S.

Inspector-General of Civil Hospitals, Bihar and Orissa.

THERE were 485 hospitals and dispensaries open on January 1 and 546 on December 31, 1923, an increase of 61.

The total number of patients treated at the State, public, local fund and private-aided dispensaries was 3,586,552.

DISEASES.

The year under review was a healthy one. The death-rate was 25·0 per mille compared with 24·1 in the preceding year. This slight increase was probably due to malaria and plague which were prevalent in certain districts.

The total number of deaths from cholera decreased from 26,805 to 8,198.

Plague was much more prevalent in 1923 than it was in the previous year; the death-rate per mille rose from 0·4 to 0·8. Certain districts of the Patna and Tirhut divisions were chiefly affected.

Small-pox was prevalent in certain districts during the year and the deaths increased from 2,560 in 1922 to 3,161.

Deaths from malarial fevers rose from 578,656 in 1922 to 599,840 in 1923. The total number of patients treated for malaria in hospitals and dispensaries was 932,508.

Quinine can be bought at offices of civil surgeons and sales are gradually increasing since the price of the drug fell.

26,439 patients were treated for influenza in hospitals and dispensaries in 1923. Vaccine was provided by Government to all civil surgeons and superintendents of jails, free of cost, and was available whenever required.

The total number of patients treated for the venereal diseases was 64,172. A special grant of Rs. 12,000 was made for the purchase of special drugs used in the treatment of syphilis. This grant was distributed to all Sadr and police hospitals and to many subdivisional dispensaries.

Rai Bahadur Dr. P. N. Das continued his investigation in connection with filariasis and read a paper at the Indian Science Congress on the results of his previous year's work. Ninety-two cases were treated by him in 1923, against 90 in 1922, with good results. A special hospital for the treatment of these cases has been built and equipped at Puri.

The number of cases treated for kala-azar increased from 17,212 in 1922, to 20,619. This increase is probably due to patients coming to hospitals more freely for treatment and not to an increase in the prevalence of the disease. The treatment by intravenous injection of various drugs appears to be increasing in popularity in many of the districts where the disease is prevalent.

The cases treated in hospitals and dispensaries for tubercle of the lung numbered 8,924 against 6,825 in 1922, and deaths among them were 131 and 116 respectively. There are no special hospitals for the treatment of these cases.

Ankylostomiasis is prevalent all over the province—the northern districts appear to be more heavily infected than others. During the year a special investigation was commenced by Dr. Korke in the Singhbhum district under the auspices of the Special Research.

In the ten leper asylums at work during the year there were altogether 2,082 resident lepers against 2,010 in 1922.

The buildings of the Ranchi Radium Institute have been completed and equipped. The successful treatment given in past years has drawn a large number of patients, and the rise in figures will show that the work of the institute is greatly appreciated. There were 189 new cases treated in the year under report against 86 in 1922.

Colonial Medical Reports.—No. 181.—Sudan.

ANNUAL REPORT OF THE SUDAN MEDICAL SERVICE ON CIVIL MEDICAL WORK IN THE SUDAN, FOR THE YEAR 1924.

General Considerations and Progress.

Considerable progress has been made along the lines laid down in last year's annual report, with a view to bringing medical help to the main mass of the population for the most part situated out of reach of the hospitals.

It is hoped thus not only to improve the general health and efficiency of the population and to prevent loss of life from endemic and epidemic diseases, but also in the less sophisticated areas by gaining the confidence of the people, to materially aid the administration and the development of the country.

Dispensaries and Assistant Medical Officers.

Seven assistant medical officers were passed out in the early part of this year and sent to dispensaries in various parts of the Sudan.

New dispensaries have been opened at Goz-Rageb in Kassala Province on the Atbara and at Karkoj in the Fung Province; the former to reach the large number of nomad Arabs who come down to the river from the Butana during the dry season, the latter to reach the people in a populous district which is becoming an important cotton growing area, and where kala-azar, malaria, bilharziasis and ankylostomiasis are endemic.

Two travelling dispensaries have been opened at Hillet Nuer and Abwong respectively, the assistant medical officers in question travelling round with the district commissioners and treating all sick who may collect. The sick treated on these tours are for the most part cases of syphilis and yaws, with a certain percentage of wounds, ulcers and eye diseases.

Dispensaries are also in course of construction at Talodi and Gebelein and will be opened at the beginning of next year.

Twenty small dispensaries are in course of construction or are already constructed in the irrigated area of the Gezira, one dispensary being placed in the centre of each 5,000 feddan block. Twenty sanitary hakims are in course of training for work in these dispensaries. Three of these dispensaries have already been opened and are doing very good work. The time of the sanitary hakims of these dispensaries will be divided between anti-mosquito work and the treatment of sick.

Anti-bilharzial Work.

Marked progress has been made with the anti-bilharzial campaign in Dongola Province, and there is every reason to hope that the disease will be stamped out in this Province in the course of the next two years. The great difficulty is the lack of adequate British supervision. It was only possible to spare a medical inspector for this work for two months during the year under report. It is hoped that a medical inspector will be able to be spared for four months during the ensuing year. The work is one of the utmost importance, as it is desired to prevent this disease spreading from this important reservoir of labour to the irrigated area of the Gezira. This would be a disaster.

Ankylostomiasis.

An ankylostomiasis survey has been commenced in Dongola Province, where this disease is known to be prevalent. It is hoped that it will be completed in the course of this winter and that a large number of the cases will by then have been cured.

Trachoma.

An especial effort has been made to deal with trachoma (Egyptian ophthalmia) in Dongola Province during the last year, but it is doubtful if any real progress can be made until a larger subordinate staff and increased British supervision can be provided.

Senna Dam Works.

Under this heading is considered the work at Makwar and the work on the main canal as far as Hag Abdulla. The results obtained during the past year have been extremely satisfactory. The malaria admission rate among the Egyptian labourers, who are the susceptible element, was further reduced to 1 per cent., and this in spite of the fact that the rainfall was an exceptionally heavy one, and that the first batch of labourers were brought up at the end of September instead of at the end of November, as in the previous year. The successful nature of these results is the more striking when it is remembered that Makwar used to be a malarial swamp of a very virulent type during the high Nile and the rainy season.

School of Medicine.

The opening of the School of Medicine took place last February. The ten students at present under training are reported to be making very good progress with their first-year subjects. It is hoped that it will be possible to admit a further class of students for training this January, when the present class has completed its first year's studies. The medical and surgical work at Khartoum and Omdurman Civil Hospitals has been reorganized with especial reference to the teaching work at the School of Medicine.

Syphilis.

Every hospital and dispensary carries out anti-syphilitic work. 22,260 injections of novarsenobenzol have been administered during the year. About half

of the work of the outlying dispensaries is anti-syphilitic work. There is reason to believe that the incidence of this disease has definitely diminished during the last eight years in the Northern and Central Sudan. In the areas in which anti-syphilitic work has been actively carried on during the last ten years, such as Omdurman and the Blue Nile Province, there appears to be no doubt that far fewer cases of primary and secondary syphilis are presenting themselves for treatment. It is not, however, possible to give definite figures to support this conviction.

Tuberculosis.

Two hundred and ninety cases were admitted to hospitals for tuberculous diseases during the past year The percentage rate is not increasing and this in spite of more accurate diagnosis.

It is believed that this disease is not on the increase, and that it will tend to decrease as the general standard of living improves and as malaria, worm infections and other debilitating factors are gradually got under control.

Dysentery.

There is a steady increase of the total number of cases, and in particular an increase of the number diagnosed as bacillary dysentery. The total increase is due to two factors: (i) The increased willingness to come to the hospitals for treatment; (ii) The increasing accuracy in diagnosis in out-stations. A great many cases which were formerly reported as diarrhœa are now reported as dysentery. This particularly applies to bacillary dysentery. The number of bacillary cases attending provincial hospitals is still very much understated.

The rise of the total cases from 531 in 1923 to 716 in 1924 is very marked. It will be necessary to watch the incidence of this disease very carefully, with a view to ascertaining if this increase is due to the reasons given above or if there is some other factor or factors involved.

Kala-azar.

This disease is endemic in the neighbourhood of the Blue Nile above Sennar, on the Dinder and the Rahad. The population in this region appears to be partially immune. The cases reported nearly always occur in people born and brought up in some other part of the Sudan, who spend a shorter or longer period in this endemic area. Thirty-two cases were seen in Singa district alone in the last nine months and there is reason to suppose that a far larger number of cases exists. An endeavour is being made to collect further evidence on this question.

Leprosy.

The information obtained is of necessity very incomplete, and especially so in the southern provinces where the tribes are not under close administrative control.

There appear to be many more cases in the Southern Sudan than in the Northern and Central Sudan. As regards the Southern Sudan, the disease appears to be widespread, but very little can be done until the confidence of the native has been more fully gained by the spread of general medical work. Later it may be possible to induce the natives to attend daily for out-patient treatment at hospitals in the few cases where they happen to be within reasonable reach of a hospital; or if too far away, to consent to be admitted to special leprosy wards or hospitals as in-patients. Every effort is being made, however, to treat patients with the resources at present at our disposal.

As regards the Northern and Central Sudan, the incidence of this disease appears to be much lower. The disease does not seem to be spreading and the position is not in any way very alarming.

At present, although the treatment of leprosy has made considerable strides, we are still not in possession of any specific cure. When a cure for leprosy has been discovered in any way comparable to its effect on this disease to that of novarsenobenzol on syphilis, then no stone will be left unturned to bring this cure within reach of every affected native, both in the North and in the South, but in particular in the South, where the disease is most dangerous.

Influenza.

This disease was widespread in the early months of the year, but the type was not severe and but few deaths occurred.

Malaria.

Owing to the more favourable spacing of the rains in the rainy season of 1923 the malaria incidence was not heavy. A severe local outbreak of malaria occurred at Nuri owing to extensive mosquito breeding taking place in the large number of pools left by the falling Nile and in wells. This in reality is attributable to lack of British supervision owing to shortness of staff.

Cerebro-spinal Meningitis.

Severe outbreaks of epidemic cerebro-spinal meningitis occurred in the Fung Province in March and September. 603 cases were reported with 138 deaths. The true totals were in all probability much higher.

Dengue Fever.

An outbreak of dengue fever occurred at Atbara in the early months of the year.

LEPER ASYLUM AT OMDURMAN.

This asylum is under the administration of the Sudan Medical Service, but the doctors of the Church Missionary Society hospital very kindly undertake the care and treatment of the patients.

Seventeen patients were admitted during the year, two were discharged as non-infectious and six died. There were twenty-eight patients in the asylum at the end of the year, fifteen of whom were men and thirteen women.

Fifteen of these have been found to be non-infectious and will be discharged as soon as arrangements can be made for their maintenance after discharge.

Colonial Medical Reports.—No. 181.—Sudan (*continued.*)

Two hundred and fifty-six intramuscular injections of moogrol were administered. The doctor in charge notes considerable improvement in the general condition of the patients. He attributes this largely to the more liberal diet given in the leper asylum; patients before admission are often very undernourished—but he thinks that the moogrol injections have also contributed to this improvement. He is not, however, enthusiastic as to the results obtained by the use of this drug.

EPIDEMIC JAUNDICE.

An outbreak of epidemic jaundice occurred in an isolated working party at Railhead during the months of February and March, 1924. Ten cases, including one British inspector, attended for treatment. Six of the cases were mild and were treated at Railhead; the remainder were evacuated at Atbara and Port Sudan. The following short summary of the symptoms, &c., by the Medical Inspector in charge at Railhead, is of interest:—

Symptoms.—Attacks were preceded by either diarrhœa or constipation.

The illness generally started with a rise of temperature, headache, lassitude, loss of appetite, and nausea.

Vomiting.—Occurred in half the cases.

Pain.—Four of the patients had considerable pain and tenderness in the epigastrium and right hypochondrium.

Liver.—Was definitely enlarged in three cases.

Fever.—Temperature rose abruptly to 100°-101° F. at onset and remainder between 99°-100° F. for about seven to eight days.

Stools.—Pale in colour—in three cases definitely clay-coloured.

Urine.—Highly coloured—bile salts present—no albuminuria.

Jaundice—Present in all cases at some stage.

Usually became obvious on third or fourth day of illness and continued for nine to ten days.

Complications.—One case treated at Port Sudan Hospital relapsed on return to Railhead.

He had all the above signs and symptoms, but his liver was not enlarged. He developed acute ascites and died from heart failure.

The remaining cases made an uninterrupted recovery.

Causation—No definite cause for the outbreak could be traced.

The epidemic was confined to this party of fifty men.

Their food and water supply was from the same source as for the main camp.

Flies were very prevalent in this area, but not more than elsewhere.

Colonial Medical Reports.—No. 182.—Bengal.

ANNUAL REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES UNDER THE GOVERNMENT OF BENGAL, FOR THE YEAR 1923.

By R. HEARD.

Surgeon-General with the Government of Bengal.

CALCUTTA HOSPITALS AND DISPENSARIES.

Number.

Twenty-four hospitals and dispensaries were working in Calcutta at the beginning of the year under report. During the year two new institutions were opened, viz., the Entally and the Taltola Municipal Dispensaries which treat out-patients only, thus raising the total number of institutions to 26 in the latter part of the year. Seventeen of these institutions have indoor accommodation while the remaining nine treat out-patients only.

Beds.

The total number of beds provided in the 17 indoor hospitals was 2,903 as against 2,857 in the previous year. The Sree Vishudhananda Saraswati Marwari Hospital, a private non-aided institution, showed an increase in its beds from 35 to 83, and the Medical College Hospitals provided 8 more beds. On the other hand, in the Campbell Hospital there was a decrease of 10 beds owing to the conversion of one of the annexes into a theatre for septic operations. Thus there has been a net increase of 46 beds.

Patients Treated.

The total number of patients treated during the year was 416,019 (40,755 in-patients and 375,264 out-patients) as against 438,899 (39,867 in-patients and 399,032 out-patients) in the previous year, or a decrease of 22,880 patients during the year. There was an increase of 888 in-patients, but a decrease of 23,768 out-patients. The introduction of the system of charging small fees in the Medical College, Campbell, Sambhu Nath Pandit and Presidency General Hospitals, together with the comparative absence of epidemics, accounts for this falling off in the attendance of patients during the year. There was a noticeable increase of attendance in the out-door departments in the Carmichael Hospital for Tropical

Diseases, the Kidderpore Municipal Dispensary, the Chitpur Dispensary, the Carmichael Medical College Hospitals, Belgachia, and the Sree Vishudhananda Marwari Hospital, where the system of charging fees was not in force. There was no marked increase or decrease of in-patients in the other hospitals.

The death-rate among in-patients remained practically at the same level as in the previous year, viz., 11·26 per cent.

Diseases.

Cholera.—The outbreak of cholera in 1922 was of a mild character as compared with the epidemic of 1921. In 1923, the total number of in-patients treated was 1,302 with 274 deaths as against 1,527 with 311 deaths in the previous year. The number of out-patients treated in 1923 was 161 as against 226 in 1922.

Kala-azar.—The prevalence of this disease is becoming more and more revealed, and 5,599 patients were treated as against 2,940 in 1922. The results of treatment with antimony are reported to be very good, and the popularity of this treatment accounts for the increase in admissions to these hospitals.

Malaria.—With the exception of diseases of the eye, malaria was responsible for the largest attendance, although the total number of cases treated during the year under review fell from 42,342 in 1922 to 33,980 in 1923. The total number of in-patients treated in all the hospitals was 2,226 and the death-rate was 4·58 per cent.

Small-pox.—The incidence of small-pox was low; only 108 cases were recorded in the Calcutta hospitals as against 356 in 1922. The number of in-patients treated was 76 with 21 deaths as against 283 with 96 deaths in 1922.

Influenza.—This disease was present in sporadic form throughout the year. The incidence of the disease has been gradually decreasing since the epidemic in 1918, the number of patients having fallen from 16,784 in that year to 6,447 in 1923. The mortality from this disease was 15·74 per cent.

Plague.—The number of plague patients treated in the Calcutta hospitals was 29 as against 71 in 1922. The mortality was high, the average death-rate being 92·30 per cent.

Tubercle of the Lung.—The attendance of patients suffering from this disease was greater than that in the previous year, viz., 3,251 as against 2,595. The number of in-patients treated was 790, and the average death-rate 51·52 per cent.

Venereal Diseases.—The total number of patients treated for venereal diseases was 19,782. Of the former number, 5,436 males and 2,100 females suffered from gonococcal infection and 6,232 males and 2,301 females from syphilis, while 2,749 males and 964 females suffered from other forms of venereal diseases. The total number of in-patients treated during the year was 1,699.

Diphtheria.—One hundred and thirty patients were treated in the Diphtheria Ward of the Medical College Hospitals, with a mortality of 23·07 per cent. Tracheotomy was performed in 50 cases, of which 28 ended fatally.

DISTRICT HOSPITALS AND DISPENSARIES.

The number of dispensaries in 1922 was 859. During the year under review 60 new dispensaries were opened and 5 were closed, a net increase of 55 dispensaries as compared with 32 in the preceding year, and the number of dispensaries at the end of the year was 914.

The system of subsidizing private medical practitioners was also adopted in the districts of 24-Parganas, Faridpur, Dinajpur and Khulna, and 9,212 patients were treated under this arrangement, the number of private practitioners subsidized being five.

The number of homœopathic dispensaries in existence during the year was 27, 13 Ayurvedic dispensaries and only 2 Unani dispensaries, in which 64,860 patients received treatment.

Patients Treated.

The number of patients treated in mufassal areas in allopathic institutions was 7,082,603, and includes 182,248 patients treated at dispensaries opened during the year under report.

As usual, the largest number of patients treated suffered from malaria, viz., 2,101,954. Next come in order of frequency diseases of the respiratory system other than pneumonia, tubercle of the lungs, diseases of the eye and ear, and of the stomach and intestines. The total number of patients who sought medical relief in the indoor wards of all classes of hospitals (allopathic) was 61,975, with a mortality of 6·38 per cent.

Diseases.

Malaria.—Slightly over one-third of the total number of patients treated in the district hospitals and dispensaries suffered from malaria. Altogether 2,101,954 patients were treated as against 1,988,577 in 1922. The largest number of malaria cases occurred in the districts of Burdwan, Rangpur, and 24-Parganas. Treatment by injections of quinine bihydrochloride was largely resorted to, and satisfactory results are reported. During the year 1,736 lb. of quinine-sulphate (value Rs. 46,937) were sold by the Juvenile Jail to charitable hospitals and dispensaries under Government supervision. The Director of Public Health, Bengal, also distributed to these dispensaries free supplies of quinine and cinchona febrifuge.

Influenza.—Altogether 51,769 patients were treated as against 62,152 in 1922. The greatest number of cases occurred in the districts of 24-Parganas (6,955), Mymensingh (6,342), Murshidabad (4,466), and Hooghly (4,399).

Cholera.—There were only 8,389 cases of cholera as against 9,475 in 1922. Altogether 241 deaths were recorded as compared with 332 in 1922. The disease was most prevalent in Dacca district.

Small-pox.—From the statistics received it appears that the epidemic of this disease, which broke out in 1919 and persisted in 1920, has been steadily decreasing. The number of cases has fallen from 1,848 in 1920 to 282 in 1923. The total number of deaths recorded was only 10 as against 15 in 1922.

Venereal Diseases.—The total number of patients

treated for venereal diseases was 82,575 as against 78,957 in 1922. Treatment with arsenobenzol preparations has proved satisfactory.

Tubercle of the Lung.—The number of patients treated for this disease rose from 6,262 in 1922 to 6,827 in 1923. In the two previous years, viz., 1920 and 1921, the numbers were 5,824 and 5,805 respectively.

Kala-azar.—Cases of kala-azar are being diagnosed in increasing numbers. The number of patients treated in 1923 was 34,264 as against 15,566 in 1922. The disease is generally diagnosed by the aldehyde test, and the usual treatment is with injections of antimony preparations. Injection of a two per cent. solution of potassium-antimony tartrate or sodium-antimony tartrate is commonly employed, but the former is regarded as more satisfactory. In many districts training centres have been opened to impart instruction in the diagnosis and treatment of this disease. The greatest number of kala-azar cases was found in the Mymensingh district. It is reported that a few years back the disease was unknown in Mymensingh, but now it is found to be present everywhere in the district. The disease is prevalent in the districts of 24-Parganas, Noakhali, Dacca, Tippera, Hooghly, and Nadia.

Leprosy.—Altogether 4,144 patients were treated for leprosy, viz., 713 in the special Leper Asylums at Gobra, Raniganj, and Bankura, and 3,431 in general hospitals and dispensaries. The corresponding figures for the previous year were 804 and 1,385 respectively.

GENERAL.

The year under review has been marked by a rapid increase in the number of dispensaries, the District and the Union Boards playing a conspicuous part. The general health of Bengal was better than in the two previous years. The financial condition of many mufassal institutions, has, however, been unsatisfactory. In some places civil assistant surgeons have been replaced by sub-assistant surgeons, and in others, sub-assistant surgeons have been replaced by private practitioners. Subscriptions in many cases have remained in arrears. The introduction of the system of charging small fees has not been popular; in some districts it has led to an increase of income, but in others it has seriously interfered with the collection of subscriptions.

Colonial Medical Reports.—No. 183.—British Guiana.

ANNUAL MEDICAL REPORT FOR BRITISH GUIANA FOR THE YEAR 1923.

By P. JAMES KELLY,

Surgeon-General.

PUBLIC HEALTH (GENERAL.)

THE population of the Colony on December 31, 1923, was estimated at 299,199. There were 9,109 births and 8,468 deaths.

GENERAL DISEASES.

(*a*) *Tuberculosis.*—The number of deaths registered as due to tuberculosis was 394.

The Society for the Prevention and Treatment of Tuberculosis established in 1907, has, as usual, rendered good and efficient service.

There are Tuberculosis Dispensaries in Georgetown and New Amsterdam, and Tuberculosis Clinics are regularly conducted in rural Medical Districts at Schoon Ord, West Bank, Demerara, and Buxton, East Coast, Demerara.

The Tuberculosis Hospital at Best (near Georgetown) designed for the treatment of early cases of tuberculosis, has had under treatment during the year 28 males and 11 females. There were 7 deaths—4 males and 3 females.

(*b*) *Enteric fever.*—There were 476 cases of enteric fever notified in the whole Colony and 117 deaths.

During the year 4,026 doses of typhoid-para-typhoid vaccine were supplied by the Bacteriological Department.

(*c*) *Diphtheria.*—Thirty cases were notified during the year with 6 deaths. Ten of these cases and 3 deaths occurred in Georgetown.

(*d*) *Chicken-pox.*—The number of cases notified was 29, of which 8 were in Georgetown.

(*e*) *Pneumonia.*—The mortality from pneumonia was 772.

As in the previous year a large proportion of these cases was of influenzal origin.

(*f*) *Bright's disease.*—The number of deaths from Bright's disease and acute nephritis was 780 and 61 respectively.

LOCAL TROPICAL DISEASES.

(*a*) *Malaria.*—The deaths registered as due to malaria numbered 1,080.

The number of deaths from malaria in Estates Hospitals was 120.

The Mazaruni and Potaro River areas, where the diamond and gold fields exist, are unfortunately highly malarious and a large percentage of miners contract the disease while engaged in these industries. With the further development of these mining areas and an

increased mining population it is anticipated that the Colony's malarial statistics will be materially influenced for the worse. The type of malaria contracted in these regions is usually of the subtertian variety with severe gastric and intestinal (malarial dysenteric) symptoms.

(*b*) *Ankylostomiasis.*—With the introduction of carbon tetrachloride the disease is being kept under better control, especially on sugar estates where routine examination of estate labourers is made by the medical officers. The number of cases treated in Government and Estates Hospitals during the year is 651.

(*c*) *Dysentery.*—This disease is most prevalent in the rainy season from November to February.

The number of cases treated during the year was 936. This disease is mostly of the bacillary type. Some cases of amœbic dysentery occur and some that conform to neither species.

Onderneeming Industrial School for Boys.

The daily average number of boys was 159·6 and of this daily average the percentage sick amounted to 2·98. The chief diseases were malaria, fever and ulcers. There were 37 cases of malaria. There were 5 cases of blackwater fever. Ankylostome infection has been controlled by routine inspection and treatment. In December, 1923, the percentage infected was 7·8. The number of cases transferred to the Public Hospital, Suddie, for treatment was 36.

Urban Districts.

In the City of Georgetown there were 1,883 births. There were 1,583 deaths. The infant mortality was 184 per 1,000 registered births. There were 168 notifications of enteric fever and the number of deaths was 40. Malarial fever was the cause of 63 deaths in the city.

Filaria.—The number of cases with deaths due to filariasis during the year was 298 and 11 respectively.

The total number of deaths registered in the Colony was 55.

In this connection a special report has been published by the London School of Tropical Medicine —"Research Memoir Series—Volume V, Memoir 7, 1924. Filariasis in British Guiana. (A Report of the Filariasis Commission, 1921)."

Rural and Village Areas.

Sanitation, as in the previous year, is much handicapped owing to physical and meteorological conditions. The lack of proper drainage in the inhabited areas of the low-lying coastal belt and the consequent accumulation of stagnant water, furnishing mosquito-breeding areas, are the main problems to be contended with.

Malaria is the most prevalent disease and is particularly fatal in the case of infants, due to its assuming the cerebral type.

The drinking-water supplies, except where artesian wells exist, are not satisfactory, especially in periods of drought. The best solution of this problem is dependent on the extension of artesian well-water supplies.

The latrine systems and disposal of sewage in rural areas are also defective and the situation is complicated through periodical floodings and lack of proper drainage.

Annual Report of the Government Medical Officer of Health for the Year 1923.

Introductory.

Preliminary remarks as to the Colony's position and the physical features of the inhabitated portion were introduced into the report for the first time in 1922. That information has this year been summarized.

The year 1922 was remarkable for its very moderate rainfall throughout the middle portion of the year. The "long wet season" of May, June and July was represented by moderate rain at intervals and none of the usual flooding occurred. The later rains were delayed and before their arrival in December the shortage of water had begun to be felt in several districts.

The very heavy rain of December once more emphasized the urgent need of drainage of the coastlands. Deep inundation of many villages occurred.

The past year will always be historic in the health matters of British Guiana. In 1923 the prolonged negotiations for the sewering of the capital were completed and the contract for the work was signed. In that year also were initiated definite schemes for the drainage, irrigation and water supply of the coastlands.

Of the total deaths in 1923 (whole Colony) 1,080 were due to malaria, 117 to enteric fever, 1,165 to bowel complaints other than enteric fever, 710 to diseases of early infancy, 842 to kidney diseases, 394 to tuberculosis, and 55 to filaria.

Notes on Principal Diseases.

Malaria.—The deaths registered as directly due to malaria numbered 1,080.

This heavy mortality and the vast, though unrecorded, loss of working efficiency and of working time which malaria causes year by year are features of the Colony's life whose importance has long been urged by members of the medical service but which hitherto has not been grasped by the public.

Recent speeches by public men show that the idea still prevails that malaria prevention is an affair for the doctors. It cannot be too emphatical'y stated that it is no longer so. The way has been pointed out, the methods have been elaborated and the results of inaction have been proclaimed in and out of season. There is one essential, without which anti-malarial work in this Colony is like ploughing the ocean, namely, good main drainage. This is, perhaps, at last in sight, but when that is accomplished there will still be required a vigorous public opinion to strengthen the hands of those who must see to the carrying out of what Dr. Wise in 1919 called the "small, petty, irritating details, ... small in themselves but of vital importance in the war with malaria."

Colonial Medical Reports.—No. 183.—British Guiana *(contd.)*.

The conscientious carrying out of such duties is still resented by many of the people and by some of their representatives as unwarrantable interference with personal liberty.

Enteric fever (including paratyphoid).—This disease did not assume epidemic character during 1923.

Sex incidence of enteric fever was in the proportion of 100 males to 69 females, the respective numbers notified being 175 males and 121 females.

The age incidence showed the usual preponderance of cases during the years of childhood, adolescence and early adult life. 71 per cent. of all cases were between the ages of 6 and 30 years. The usual disinfection of premises and chlorination of water vats after the occurrence of cases of enteric were carried out.

Tuberculosis.—459 cases were notified, with a death rate of 1·3 per 1,000 persons living (whole Colony).

The Society for Prevention and Treatment of Tuberculosis has carried on its usual work of combating this disease. Throughout the year the Government Medical Officer of Health has been the Honorary Secretary and a visiting Physician of the Society. The Annual Report of the Society contains a full account of the work in connection with this disease.

Other infectious diseases were notified as follows, diphtheria 30; chicken-pox 29; cerebro-spinal meningitis 1; and alastrim 1.

Leprosy.—Throughout the year the Medical Officer of Health has visited discharged lepers from time to time. The conditions under which the rural population of British Guiana lives are seldom if ever such that satisfactory home isolation can be carried out. It would be better to discharge from the asylum only those cases in which the disease has been definitely arrested.

Ankylostomiasis.—Colonial statistics are not available, but the frequency of infection admits of no doubt. Little diminution is to be looked for until satisfactory conservancy is the rule instead of the exception; and fair conservancy for country districts will for the first time become a practicable proposition when the drainage works now foreshadowed are an accomplished fact. Where it is possible to combine therapeutic and preventive measures this disease has in this Colony as elsewhere been kept down to a minimum.

Notes on Leprosy and its Treatment, from Observations made in the Leper Asylum, Mahaica, during the Year 1923.

Plea for an Anti-leprosy Campaign.

The vast majority of cases of leprosy admitted in this asylum are in an advanced stage of the disease. This is very regrettable, as in this way any specific treatment that may from time to time be advocated elsewhere is given here but a poor chance. Further, no effective control of the disease can be hoped for if lepers are left at large for such a long time before they are isolated in the asylum or elsewhere, and properly treated.

A local anti-leprosy campaign was suggested to the Government. This should start with a systematic search for lepers at large, throughout the Colony; this search should be missionary in character, and not such as to suggest in any way a police hunt; its object, fully explained beforehand to the public, should be chiefly to bring within the reach of every leper in the Colony the most successful treatment of the disease. In suitable cases opportunity could be given to patients to be treated in their village, under conditions of proper isolation. In other cases patient explanation and gentle persuasion very often will succeed to make the patient decide to seek admission in the asylum, even before the machinery of the law is put into action to compel him to do so.

It might be pointed out here that a few lepers have voluntarily walked into the asylum, and come to me for treatment. One of them stated that, apart from any hope of improving under the treatment, he thought the asylum was the best place for him, as he was afraid of passing on the disease to his family if he remained at home.

Education of the people, hence, may be a valuable help towards stamping out the disease from the country; it may bring more patients to the asylum, and, above all, it will make them come earlier.

It was also suggested putting into effect one of the recommendations made (indirectly) by the Leprosy Relief Association; the periodical examination of the members of the family of every leper—with this modification, that instead of limiting this examination to "members of the family" it be extended to all the "contacts," that is to every person who has been in close association with the leper.

Early Diagnosis.

This is of course of prime importance, from the point of view of treatment; the opinion of recent observers is that leprosy is non-infective in the early stages, so that isolation does not seem to be imperative then.

Prodromata has been described. In the case of nodular leprosy: pyrexia, dyspeptic troubles, drowsiness, epistaxis, profuse sweating. I have been able to trace one or more of these symptoms, from the history as told by the patient, but they do not occur with regularity or constancy; also, they are common to so many other conditions. In the case of maculo-anæsthetic leprosy, shooting pains (or "lancinating") may occur very early, and are often described by lepers as rheumatism.[1]

These prodromata, apparently of little use, considered by themselves, to the clinician may assume some diagnostic importance if associated with a family history of leprosy in particular cases.

A few inmates declare that they suffered from a persistent cold in the head for some time before any definite signs of leprosy made their appearance. In view of the possibility of the transmission of the disease (or, at least, one of the modes of transmission)

[1] Other early signs: (1) Bullæ on the extremities, resulting in sores; (2) Starting contracture of fingers, with bending of little finger.

occurring through the naso-pharyngeal mucosa, this information gathered from inmates is worth while recording.

Differential Diagnosis from Syphilis.

The initial manifestations of maculo-anæsthetic leprosy—the leper spot, or spots, associated, perhaps, with lancinating pains—may give rise to a mistaken diagnosis. This has positively happened, and it may not be without prejudice to the patient. Once syphilis is suspected, the blood is tested, and if a positive Wassermann is obtained the diagnosis is considered as confirmed, and novarsenobillon is injected.

Now a positive Wassermann test is often obtained in leprosy. Further, novarsenobillon, or arsenic in other form seems to be harmful to maculo-anæsthetic lepers.

Novarsenobillon has been tried in a few cases; in the maculo-anæsthetic cases it aggravates both the anæsthesia and the ulcerations, or the maculæ (these extend). In one case, liq. Fowleri has the same effect. As these observations have been made only on a small series of cases they may not seem very conclusive. However, it must be remembered that both arsenic and the *Bacillus lepræ* cause peripheral polyneuritis, hence it is not surprising that the former tends to aggravate a condition caused by the latter.

Hence the differential diagnosis between leprosy and syphilis is not without importance. As this is one of very few exceptions to the specific value of the Wassermann test, if borne in mind, it may not often be the cause of a mistaken diagnosis. A nasal smear will clear up the doubt. Also leprous sera react with tuberculin, whereas syphilitic sera do not —according to some observers.

The Initial Eruptions of Leprosy (and their Relation to other Symptoms).

It seems that when the leper spot comes out, diagnosis is relatively easy.

In nodular cases this initial eruption is an erythematous patch, red or reddish-brown in negroes, purplish in fair persons; it is generally roundish, varying in size, but often about an inch in diameter; it is raised above the surface, and the edges are sharply marked; it is often tender, or "burning."

This "leper spot" appears most often on the face, cheek or forehead; on the outside of the thighs and on the hips; sometimes on the anterior aspect of the forearms. After a variable interval the spot (or spots, as more may follow the first one) may disappear, or almost disappear, to be followed by the appearance of nodules, on the same spot or elsewhere.

In the maculo-anæsthetic cases, the initial eruption is a yellow roundish spot, well defined, but not raised above the surface; it becomes numb later on. The site of the eruption seems to be more variable than that of the eruption of nodular leprosy; it is often on the hip or on the face, but also on the chest, back, hands and knees.

In some cases the spots are anæsthetic from the first, but often they do not become so until some time afterwards—may be several months after their appearance. However, anæsthesia in the extremities (as distinct from that in the patch itself) is usually an early sign; this loss of feeling in the fingers, generally those innervated by the ulnar nerve, is detected early by the patient.

Loss of muscular power appears later on. Atrophy of the interossei muscles of the hand, resulting in the "main en griffe" is one of the most common results.

After a variable time (from the appearance of the "spots,)" often a couple of years, the spots enlarge peripherially, their edges become raised and often studded with very small vesicles. These enlarged patches are pale-whitish in colour, dry and numb. This is soon followed by deformity, mutilation, and the formation of trophic ulcers.

Mixed leprosy generally begins as one of the forms described above, and after some time, often several years, signs and symptoms belonging to the other form are superadded. Thus it may commence as a maculo-anæsthetic case, nodular infiltration following the nervous manifestations, or vice versa. Sometimes symptoms and signs of one form may appear simultaneously with those of the other form. Thus a nodular leper spot may appear on the face, and anæsthesia in the fingers.

Transmission of the Disease.

The theory of heredity, in a scientific sense, is not supported by facts as far as can be gathered from past and recent literature—unless it is changed into "hereditary predisposition," when the position will become similar to that of tuberculosis. No doubt leprosy runs in families, as shown by many cases in this asylum; this may only mean that members of the same family are in a favourable condition for the transmission of the infection from one to the other.

It seems that in one or two cases, children born in this asylum, and removed from the mother immediately after birth, have contracted the disease afterwards. No exact data are available, and of course there is nothing to prove that these children did not contract the disease outside the institution, through prolonged contact with a leper.

Whatever the usual mode of transmission may be, it seems very probable that in some cases the disease has been contracted through sexual intercourse; the history of these cases point very clearly to this. If this danger were known to the public, it would exert some restraint on the spreading of venereal disease, besides possibly helping to control the spread of leprosy itself.

Aboriginal Indians free from Leprosy.

No case seems to have ever occurred of an aboriginal Indian contracting leprosy. Among other persons, missionaries have passed several years among these Indians, but they never saw any of them afflicted with anything like leprosy.

It may be mentioned here that the worst case in this asylum is that of a young Boviander girl; she is covered with ulcers, and no treatment, however persistent, has been of any use.

It is possible that some racial immunity, however

feeble, present in afflicted races, but not in the Buck Indians, may account for the severity of this case.

Treatment—Ol. Chaulmoogræ and Moogrol.

In 1922, moogrol was used exclusively, and it was given intramuscularly, as recommended by the makers, in doses of 1 c.c. to 6 c.c. at first; later in the year the dose was boldly increased up to 10 c.c. (5 c.c. or 6 c.c. is the recommended maximum) without any ill effects.

In 1923 the intravenous method has been tried, and compared with intravenous ol. chaulmoogræ.

The intravenous method of injection is superior to the intramuscular one in some respects, it does not cause pain, indurations, or abscesses.

Ol. chaulmoogræ is not convenient for injections. It is very dense, and a large-bore needle is therefore required; and only a very good syringe can draw it up in a short time. Also when injected intravenously it causes, in almost every case, a violent fit of coughing, due, it appears, to the formation of fat emboli in the pulmonary capillaries; this may not be without dangers, considering that a good number of lepers are also consumptives.

Moogrol on the other hand is a light, mobile liquid, very easily injected through fine needles. It does not cause the violent fits of coughing mentioned above.

The effects of the two preparations are the same. In several cases, however, the action of moogrol is more decided and more rapid.

These effects confirm the conclusions drawn from the series of cases treated in 1922. Moogrol (and also ol. chaulmoogræ) is capable of improving the condition of the lepers, and its action seems to be specific. The best results are obtained in early cases.

The treatment must be persistent. In many cases, the effect of repeated courses of treatment is cumulative; patients who had improved in 1922 up to a certain stage and then become stationary for a time, showed further improvement in 1923, after another series of injections.

By course of treatment is meant a series of six injections, weekly, starting from 1 c.c., and increasing the dose by 1 c.c. every week; this is the method I adopted after some trials. Often the last dose is repeated, 6 c.c. once or twice, in cases showing a very active stage of the infection, but otherwise relatively healthy. After an interval of six weeks—during which another series of cases are being injected—cases from the first series are given a second course, and so on, modifying the method to suit the gravity of the cases and the number of patients willing to be treated.

Record syringes are exclusively used for these injections as the most suitable for aspirating oily fluids and these are accurately graduated in cubic centimetres. A few needles are kept in continuously boiling water, and used in rotation, so that a perfectly sterile needle is used for each patient.

The syringe itself is sterilized in the same way, in the first instance, and disinfected after every injection in Ac-Carbol 1 in 20

The effects observed in 1922 have been obtained again in 1923; nodules tend to soften and become absorbed, or break down and heal within a short period. Nodules that were ulcerated for some time heal up. Anæsthesia is partially relieved — the "tingling" sensation completely relieved in some cases.

The effects in early maculo-anæsthesia cases are pretty constant, and hence a probable prognosis can be attempted; the discoloured patches assume the colour of the surrounding skin, completely (or almost) disappearing; and the anæsthetic area contracts considerably, but very often a small anæsthetic or hypoæsthetic area persists. Also, the weakened hand-grip due to muscular paresis is strengthened. It is unfortunate that these early cases that come under observation in this asylum are so few.

Laboratory findings.—Very often, especially in bad nodular cases, a positive finding becomes negative after some methods of treatment, but not always so; so this may be accidental. Fragmentation of bacilli and loss of their staining properties (acid fast) have been noticed. This, however, has been known to take place in untreated lepers, and may be the result of a natural defensive process.

Conditional Discharges.

Many cases, among the maculo-anæsthetic ones, can be discharged with relative safety, but it is always desirable, and instructive, to follow up these cases for a time—hence the usefulness of conditional discharges.

At present the conditions under which district Government medical officers are willing to tolerate the return of a discharged inmate to his district are not very clearly definite, sometimes too vague, or tending to be chaotic. Perhaps something could be done to make the position clearer, so as to have some guidance in recommending discharges.

Re-admission and Relapses.

It is well to point out that a re-admission need not mean a relapse—often it does not. A case frequently met with is that of a maculo-anæsthetic inmate, free from all signs of active leprosy for a long time, but, of course, deformed and mutilated as the result of the disease, with nerves partially destroyed, atrophic patches of skin and anæsthetic areas—in other words, in a state of very poor and unstable trophism. A small trauma in such a person (a scald for example) will easily cause a purely trophic, non-specific ulcer; this superficial ulcer, plus the old anatomical changes, which nothing short of a miracle can ever cure, set in motion the machinery of the law—result, a re-admission.

A provision could be included in the asylum rules, whereby in such cases, if the medical superintendent is satisfied that the re-admitted patient is as fit to be discharged as he was before, he could be discharged in a more expeditious way than usual.

An Improved System of Recording Cases.

The adoption of the "Index Card System" of making notes on cases is suggested. It is superior to any book system, being more elastic, and affording a quick and easy means of reference for taking statistics, etc., in fact for the study of leprosy in general.

The cards will be indexed alphabetically, different colours showing the various forms of leprosy (i.e., white for nodular, blue for maculo-anæsthetic, pink for mixed).

This system will ensure uniformity in the keeping of records by the successive medical superintendents. Also it will provide a quick but accurate method of recording cases. This is very desirable as the duties of the medical superintendent are multifarious, and on some days anything, from a fight between inmates to an unreliable contractor, may distract him for a considerable time from scientific work.

Colonial Medical Reports.—No. 184.—Calcutta.

REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR THE YEAR 1923.

By H. M. CRAKE, M.D., D.P.H.,

Fellow of the Royal Institute of Public Health, Examiner in Hygiene, Calcutta University, Chief Registrar of Births and Deaths and Superintendent of Vaccination, Calcutta.

HEALTH DEPARTMENT.

Vital Statistics.

The death-rate.

The number of deaths registered during the year was 25,824, equivalent to a death-rate of 28·5 per thousand calculated on the census population for 1921. This is a slight improvement on the returns for 1922. Though slight, it is very satisfactory to be able to point to a steady and uninterrupted fall in the general death-rate of the city for four years in succession, viz., from 42·2 per thousand in 1919 to 28·5 per thousand in 1923. Though still much higher than in 1916-17, *i.e.*, the years preceding the terrible series of epidemics of influenza, the death-rate now corresponds very closely to the average rate recorded from 1910-1915. The total general mortality figure of 25,834 includes 1,745 imported deaths. Excluding these, the death-rate for 1923 becomes 26·5 per thousand. Unfortunately, as no correction for residents of Calcutta dying outside the city is possible, this cannot be accepted as a corrected death-rate. As pointed out last year, if nearly 2,000 persons already suffering from various diseases, frequently infectious in character, enter the city and die, there are probably many more immigrants also infected who recover, not to mention contacts, "carriers," &c.

These figures give some idea of the constant stream of infection which is pouring into the city by rail, by river, and by road. Obviously the prevention of epidemics in a large Oriental city under these circumstances is an extremely difficult task.

Variations in the mortality from different causes.

Plague.—A mild recrudescence of plague, which hardly merits the term epidemic, occurred and caused 77 deaths, *i.e.*, almost half the number recorded in 1922.

Cholera.—The epidemic of cholera was one of the mildest ever recorded in Calcutta. The number of deaths was only 914 as compared with 1,269 in 1922 and 1,997 in 1921. In fact it only caused 48 more deaths than the remarkably mild epidemic of 1917, which is the record for Calcutta.

Small-pox.—Another comparatively localized outbreak occurred this year also, but it was of a much milder character, the number of deaths being only 157 as compared with 450 deaths in 1922.

Influenza.—The number of deaths recorded as due to influenza was 371, little more than half the number registered in 1922. There has been a steady fall in the number of deaths from influenza for the last five years.

The mortality from other principal diseases included malaria, enteric, other fevers, dysentery, &c., tuberculosis, and measles.

The most satisfactory feature is the fall in the mortality from tuberculosis, as until this year the death-rate had been steadily rising ever since 1917.

The rise in the mortality from other fevers is probably due, in part at any rate, to the debilitating effect of the severe and widespread epidemic of dengue. As to the rise in the mortality from enteric, it is difficult to say how far this is real and how far apparent in view of the wider application of the Widal-Grunbaum reaction nowadays.

Mortality Rates and Principal Causes of Deaths Amongst Infants.

The infantile mortality rate calculated on the number of births registered was 294 per thousand, slightly higher than in 1922, when it was 287 per thousand. The correctness of this death-rate depends not merely on the accurate registration of deaths, but also on the accurate registration of births, a much more difficult task.

The total number of deaths amongst infants was 5,366, a slightly higher figure than in 1922, when 4,980 deaths were registered. As already noted, the infantile mortality for the two years is practically the same owing to an improvement in birth registration this year.

The principal causes of infantile mortality are: bronchitis, congenital debility, tetanus neonatorum, premature birth, diarrhœa and enteritis, infantile liver and other causes.

Colonial Medical Reports.—No. 184.—Calcutta (*contd.*).

One of the most striking features is the very large proportion of infants that die during the first week of life. No fewer than 1,831 or more than a third of the babies born in Calcutta die within a few hours or a few days of birth.

The birth of so many weakly babies doomed to die in such a short time is a serious problem. It is, of course, mainly due to antenatal conditions and cannot be remedied by baby clinics, milk depots, &c. With so many sickly, poorly-nourished mothers living under insanitary conditions, puny, weakly babies are inevitable. Whilst poverty is the direct cause of so many expectant women being ill-fed and badly housed, ignorance, child marriage, the purdah system and disease all combine to undermine their health. Although many premature births result from the conditions briefly noted above, there is no doubt that a large proportion are due to syphilis. Making every allowance for the well-known effect of chronic malaria in causing premature delivery, the large number of stillbirths is undoubted evidence of the widespread prevalence of venereal disease.

Amongst babies over seven days and under one month old, there were 878 deaths, equivalent to 16 per cent. of the total infantile mortality. Adding the number of deaths during the first week no fewer than 2,709 babies died during the first month. In other words, more than half the total infantile mortality occurred amongst babies under one month old. The principal causes of deaths were tetanus neonatorum 386 deaths, respiratory diseases 209 deaths, and congenital debility 147 deaths. Tetanus neonatorum is an entirely preventible disease due to "dirty midwifery." This is clearly shown by the fact that it is practically unknown amongst the thousands of babies delivered by the Corporation midwives. It is satisfactory to find that as a result of their operations, there has been a slight fall in the mortality from this disease. One is, I think, justified in coming to this conclusion, as none of the other causes of infantile mortality show any corresponding reduction.

Amongst babies one to two months old, the number of deaths was 441, the principal cause of death being respiratory diseases (bronchitis and broncho-pneumonia), which accounted for 251 deaths, or more than half the total.

At the next age-period, two to three months, a further decline in the number of deaths occurred. Here, again, respiratory diseases were the chief cause of death, there being 215 deaths from bronchitis and broncho-pneumonia out of a total of 333 deaths.

From three to six months of age 729 deaths, an average of 243 per month, occurred, whilst amongst infants six to twelve months old there were 1,154 deaths, or an average of 192 per month.

At both age-periods respiratory diseases were responsible for over half the total deaths. The high mortality from respiratory diseases has always been a striking feature of these returns. As babies, like all young warm-blooded animals, are very susceptible to changes of temperature, exposure when inadequately clothed (often naked) is probably an important factor in the etiology of these diseases. Of equal importance is overcrowding in damp, ill-ventilated rooms.

The comparatively low death-rate from diarrhœal diseases is in marked contrast. These diseases only account for 6 per cent. of the total infantile mortality. The number of deaths from these diseases gradually increases with the age of the infant, over two thirds of the deaths from diarrhœa occurring amongst children of from six to twelve months of age. This is due to the fact that breast-feeding is almost universal, and it is only as the child grows and the mother's milk is supplemented by artificial feeding that diarrhœal diseases become prevalent. In view of the notoriously dirty "sophisticated" milk sold in Calcutta, and the difficulty of keeping even clean milk fresh in the tropics, everybody in Calcutta boils their milk, the consumption of raw milk being almost unknown. This, I am convinced, is an important factor in the prevention of diarrhœal diseases amongst infants, in spite of a great deal of ignorance as to the vital necessity of storing milk in clean receptacles and protecting it from contamination after boiling.

The Birth-rate.

The number of births registered during the year was 18,212, or 20·1 per thousand, calculated on the total population. This is a slight improvement compared with the returns for 1921 and 1922, when only 17,308 and 17,349 births respectively were registered. As shown in previous reports, the only birth-rate of any value is that calculated on the number of women of child-bearing age. The peculiar constitution of the population in Calcutta with a large excess of males, and with a relatively small proportion of married women amongst the females renders a general birth-rate practically useless as an index of fertility or for the purpose of comparing local variations in the birth-rate. It will, of course, show local variations from year to year fairly accurately.

PRINCIPAL CAUSES OF DEATHS.

Cholera.

The epidemic of 1923 was one of the mildest ever recorded in Calcutta, the number of deaths registered as due to cholera being only 914 or 1·0 per thousand. The record year, 1917, with 866 deaths from cholera, only beats 1923 by a very narrow margin as the rate per thousand, calculated on the 1911 census population was ·96 per thousand, which very closely approximates the rate for this year. On studying the returns for the last thirty years, particularly when expressed graphically, it is quite clear that there is a fairly well-defined cycle which runs its course in about ten years. That is to say the annual recrudescences tend to increase in intensity year by year to a maximum and the decrease year by year to a minimum during this period. The terrible outbreak

of 1907, when there were 3,803 deaths from cholera was followed by a series of epidemics gradually lessening in severity right down to the mild epidemic of 1917. This was followed by a very severe epidemic in 1919, after which each year in turn saw an outbreak of less severity culminating in the extremely mild recrudescence of this year.

The epidemic of 1923 was remarkable for its late onset. Unlike previous epidemics, which usually show signs of lighting up in the cold weather, it was not till April that there were any indications of the approaching epidemic. This is even later than last year's epidemic, which started in March. This year's outbreak made little or no progress till May, when it rapidly reached its maximum and declined as rapidly. The acute phase of the epidemic only lasted three weeks. Although there was a slight terminal rise towards the end of June and the beginning of July, the height of the epidemic was over by the middle of June..

A very brief scrutiny of this year's list shows clearly that cholera in Calcutta is to a very great extent water-borne. Out of five wards in which cholera was most prevalent four are riparian. The only non-riparian ward is notorious for its numerous polluted tanks. Local explosive outbreaks in the vicinity of tanks are by no means rare in the suburban wards and are typical examples of water-borne disease. Fortunately, there is no epidemic disease which responds so rapidly to preventive measures, once the source of infection is traced. These local outbreaks can often be quickly controlled by chlorinating the infected tank and putting a police guard over it, and putting up extra standposts to increase the supply of filtered water.

The heavy incidence of the disease amongst Hindus, together with the fact that it is the wards bordering on the river and nullah which suffer most severely from cholera, is convincing evidence that cholera is water-borne, as the Hindu religion enjoins bathing in the river and nullah. Another, or rather the same source of danger in another form, is the unfiltered water supply. Millions of gallons of raw river water are distributed all over the city for flushing drains, waterclosets, &c. Unfortunately, particularly during the hot weather, it is freely used for domestic purposes. Unauthorized taps are to be found all over the city and unfiltered water is ladled out of reserve tanks or drawn off from ground hydrants. It is greatly to be regretted that the original scheme of Messrs. Moore and Bateman, which would have abolished this dangerous water supply *in toto*, was subsequently modified so as to perpetuate a system which is condemned in unqualified terms by every sanitarian I have met. Although I have always maintained that most of the cholera in Calcutta was water-borne, there are, of course, other sources of infection. Infection by direct contact is by no means infrequent owing to the carelessness and ignorance of friends and relatives. Soiled rags, &c., are thrown out into the street in a manner which is positively criminal. "Carriers" often apparently in good health and yet capable of infecting foodstuffs, &c., are another source of infection. They present a most difficult problem which will never be solved until a rigidly enforced system of notification, isolation in hospital and thorough bacteriological examination of all convalescents is in operation. Contamination of foodstuffs by dust and flies is another obvious source of infection, particularly the latter. It is unpleasant, to say the least of it, to think that every day throughout the year in Calcutta, there are 20,000 gumlas containing at least fifty tons of human fæces, lying exposed to the air, readily accessible to flies and polluting air, soil and water in their vicinity. I refer, of course, to the unsanitary service privies of which thousands remain in spite of the provision of sewers and water for flushing purposes. This grave menace to the public health is intensified by the disgusting methods of conservancy employed. Neither privy vault, gumla nor cesspit is ever properly cleansed. It, as appears likely from the very slow progress made in replacing them by connected privies, they are to remain for generations, a determined attempt should be made to improve them. Nothing short of the pail system and the abolition of the cesspit will be of any use. As the introduction of this system throughout the city will be a very expensive business, I am afraid there is little hope of it being taken up at present.

Lastly, a constant stream of infection is pouring into the city, and this includes a considerable number of imported cases of cholera. When these prove fatal prompt precautionary measures are taken, but when the cases recover the health department rarely receives any intimation and nothing is done to prevent the spread of infection.

It is hardly an exaggeration to say that in Calcutta at all events *cholera is essentially a disease of the Hindus.*

Out of a total cholera mortality of 914, no fewer than 792, or 86 per cent. of the total, occurred amongst Hindus. This is equivalent to a rate of 1·2 per thousand. Amongst Mohammedans, on the other hand, there were only 116 deaths, equal to 0·55 per thousand, whilst only four deaths occurred amongst Non-Asiatics and Anglo-Indians, and 2 deaths amongst Indian-Christians.

A rather unusual feature of this year's epidemic was the higher incidence amongst females, the death-rate per thousand beng 1·1 amongst females and only 0·97 per thousand amongst males. This is a reversal of the usual incidence.

The higher incidence amongst elderly women has always been a feature of these returns. It is unusual, however, to find any marked difference amongst young boys and girls. Young adult males invariably appear to be particularly susceptible. Broadly speaking, children (not infants) and old people are most susceptible.

Small-pox.

Another curiously localized outbreak of small-pox occurred during the beginning of the year. It was

much milder than the epidemic of 1922 and was even more strictly localized, being practically confined to the northern half of District I. The total number of deaths was only 157, or 0·17 per thousand, as compared with 1,450, or 0·49 per thousand in 1922.

The outbreak really began about the middle of February, when the number of deaths which had been fluctuating between five and seven per week rose to twelve. Even this slight rise was only maintained for a fortnight and then a fall occurred which lasted nearly a month. Towards the end of March a sudden rise to 19 deaths during the week ending March 31 occurred. This was the height of the epidemic, which rapidly subsided and was over by the second week of April.

This outbreak was almost entirely confined to District I, which returned 108 out of 157 deaths, or no less than 68 per cent. of the total.

A more detailed analysis of the returns reveals the astonishing fact that Wards I, II, III were responsible for 94 out of the 108 deaths in the district. Sporadic cases scattered over eleven other wards occurred chiefly in District II, where, altogether, twenty-three cases occurred. I suggested last year that the occurrence of these remarkable, localized outbreaks shortly after a severe and widespread epidemic such as occurred in 1920 might indicate a change in the epidemiology of small-pox or, at any rate, a temporary departure from the "cyclical" character hitherto such a feature of the disease in Calcutta. Possibly the vigorous vaccination campaign of 1918-20, during which about 300,000 persons were vaccinated, has had some effect in this direction. It has certainly made it difficult to push vaccination on a large scale. Local intensive vaccination, however, appears to have been a very effective measure. This resulted in each infected house being surrounded by a zone of dwellings every inmate of which had been revaccinated.

One of the most important functions of a health officer is intelligent anticipation of the probable course of events, particularly such profoundly disturbing ones as epidemics. In the case of small-pox, a study of the records of the last thirty-five years shows the following sequence of events:

(1) A "pre-epidemic" outbreak of moderate intensity.

(2) An explosive outbreak of great intensity.

(3) A non-epidemic interval of from one to four years which has never exceeded four years.

(4) During the latter part of the non-epidemic year preceding the "pre-epidemic" outbreak, a series of scattered sporadic cases occur, but unlike those in an ordinary non-epidemic year, they occur regularly week by week with hardly a break. This, in my experience, is a sure sign of the approach of a "pre-epidemic" outbreak to be followed by a severe and widespread epidemic the following year in 1921. At the time of writing the position is as follows. A severe outbreak in 1920 was followed by a typical non-epidemic year in 1921. In 1922 a most unexpected local outbreak occurred in Districts I and III. In 1923 an extremely mild local outbreak occurred in District I, *but the city was free from small-pox for several weeks during the latter half of the year.* Relying on this I confidently predicted that there would not be anything more than a mild local epidemic and possibly not even that in 1924. The probabilities are that the cold weather of 1924-25 will see a pre-epidemic outbreak of moderate intensity, but everything depends on the returns for September and October. Should a definite break of several weeks occur, however, it is just possible that the next epidemic may be postponed, but I am afraid this is hardly likely.

Plague.

The recrudescence of plague this year was a very mild one. There were only 77 deaths, or 0·08 per thousand, as compared with 144 deaths, or 0·15 per thousand last year. Last year's outbreak, following on two non-epidemic years, was an unpleasant reminder that conditions favourable to the spread of plague still flourish in Calcutta. Nevertheless, it is very satisfactory to be able to record another practically non-epidemic year. The outbreak began very late in the year. It was not till the last week of March that a slight rise in the mortality occurred, 9 deaths being recorded during the week. The following week the outbreak reached its height, 16 deaths occurring during the first week of April. By the middle of April the mortality was less than half, and though a slight terminal rise occurred towards the end of the month, the outbreak was completely over by May 12.

This outbreak was even more localized than that of 1922. Save for half a dozen sporadic cases in Districts III and IV it was wholly confined to Districts I and II, the former returning 40 and the latter 29 deaths out of a total of 77.

As previously noted, it is rather remarkable that localized outbreaks of plague rarely recur in the same locality two years running.

Measles.

Only 56 deaths were recorded as due to measles. This is equivalent to 0·06 per thousand and is the lowest rate recorded since 1915. It is satisfactory to find such a marked improvement this last two years as from 1916 to 1921 a series of epidemics occurred in which the mortality varied from 122 to 191. Prior to this series, there was a distinct tendency for rather severe outbreaks to occur followed by one or two non-epidemic years.

As in 1922 the outbreak this year commenced late and was over early. It began in March, the mortality rising to 12 or double that in February. It remained almost stationary in April and then subsided in May.

Enteric.

A further rise occurred in the number of deaths recorded as due to enteric from 413 or ·45 per thousand in 1922 to 460 or ·5 per thousand. It is

disappointing to find that the improvement in the returns in 1920 and 1921 has not been maintained. At the same time it is very difficult to decide how far the increase is real, in view of the extended application of serum tests in cases of prolonged fever.

The enteric mortality rate for the city was ·50 per thousand.

The fact that a large proportion of cases are treated at home without proper precautions against the spread of infection is undoubtedly responsible for a great deal of the enteric in Calcutta, either by direct contact or through the agency of dust and flies. "Carriers" play an important part in the spread of the disease, particularly in the case of outbreaks in schools, institutions, &c. This has been proved bacteriologically on more than one occasion. Salads and raw vegetables, which, as is well known, are usually grown in sewage-polluted soil, are another common source of infection, particularly amongst Europeans and Anglo-Indians.

Malaria.

The number of deaths recorded as due to malaria was 1,069, or 1·2 per thousand. This is almost identical with last year's figure of 1,081. These returns represent a steady improvement since 1920 and are the lowest recorded since 1917. As a correct diagnosis is often difficult it is advisable to consider the mortality from "other fevers" before coming to any conclusion as to the prevalence of malaria.

Although seasonal variations are not nearly so marked as one would expect, malarial fevers were distinctly more prevalent during the latter part of the year, i.e., after the rains. In January the mortality from malaria was 1·3 per thousand. A temporary fall to ·91 per thousand occurred in February. This curious fall in February affects practically all causes of death and is reflected in the general mortality returns. A rise to 1·4 per thousand in March was followed by a marked decline during the three months April to June, the death-rate falling to 75 per thousand in the latter month. During July and August another rise occurred to 1·3 per thousand again. This rise, save for a slight temporary decline in September, was maintained till the end of the year.

As in previous years, the death-rate amongst Mahomedans was much higher than amongst Hindus, the mortality rates being 2·6 and ·79 per thousand respectively. Although this is partly accounted for by the large Mahomedan population in the malarial wards, the difference is so marked as to suggest increased susceptibility. Amongst Indian Christians the mortality rate was ·66 and amongst non-Asiatics and Anglo-Indians only ·35 per thousand. Females were much more susceptible than males, the mortality rates per thousand being 1·6 and ·96 per thousand respectively. This is probably due to the women of the home being constantly exposed to insanitary surroundings from which the men escape for a certain number of hours every day. Young females, 10 to 15 years of age, appear to be particularly susceptible, the death-rate at this age-period being 2·7 per thousand.

Other Fevers.

The mortality from "other fevers" amounted to 2,151, or 2·4 per thousand, an increase compared with 1922, the corresponding figures being 1,801, or 2·0 per thousand. A severe and widespread epidemic of dengue occurred this year, and although the actual mortality from dengue was trifling it undoubtedly lowered the resistance of persons suffering from other diseases, particularly of this group.

This distribution confirms what has already been said about malaria and other fevers. Making every allowance for undiagnosed cases, such as malaria, kala-azar, enteric, &c., there are probably undifferentiated forms of fever still awaiting investigation by skilled research workers in tropical disease.

Dysentery and Diarrhœa.

The number of deaths from dysentery and diarrhœa was 2,734, or 3·0 per thousand, a slight increase compared with 1922, when 2,637 deaths, or 2·9 per thousand, occurred. The returns for 1922 and 1923 are a marked improvement over those for the preceding years 1918 to 1921. The diseases included under this heading are dysentery, diarrhœa, enteritis and puerperal diarrhœa or "sutika."

The returns for dysentery are almost identical with those for last year. A slight decline in puerperal diarrhœa is more than counterbalanced by a rise in the mortality from diarrhœa.

The mortality curve from this group of diseases shows a well-marked double curve, the first rise reaching its height in March, the second, a much larger one, in August. Starting with a death-rate of between 2·7 and 2·6 in January and February the mortality rose to 3·1 in March. It then declined gradually to a minimum of 2·1 in June. During July it rose rapidly and reached its maximum of 4·4 per thousand in August. The mortality remained high throughout September (3·9 per thousand). During the last quarter of the year it varied from 3·1 to 3·3 per thousand. The curves for 1922 and 1923 present a marked contrast to the average. Usually these diseases are most prevalent in January and December, when the mortality reaches its maximum, and least prevalent in June, when the lowest mortality occurs. The quinquennial average curve is V-shaped, with the point of the V in June and the limbs ending in January and December. The 1922 and 1923 curves show a rise and fall before and after the minimum in June.

Mahomedans with a death-rate of 3·3 per thousand had the highest rate of mortality. Then, rather unexpectedly, come Indian Christians, with a death-rate of 3·2 per thousand. Last year the mortality amongst Indian Christians was very little higher than amongst non-Asiatics, being only 2·2 per thousand. Amongst Hindus it was 3·0 per thousand, whilst amongst non-Asiatics and Anglo-Indians it was only 2·4 per thousand.

Colonial Medical Reports.—No. 184.—Calcutta (*contd.*).

The highest mortality rates occurred at the extremes of life. This is due to the fact that acute gastro-enteritis is common amongst infants and young children, and chronic diarrhœa is a disease of old age.

Females are particularly susceptible, the death-rate being 4·3 per thousand, as against only 2·4 per thousand amongst males.

Tuberculosis.

The number of deaths from tuberculosis was 2,089, or 2·3 per thousand, a slight decrease compared with 1922, when 2,216 deaths, equivalent to 2·4 per thousand, occurred. Slight though the decrease is, it is of great significance, as it is the first sign of improvement noted for many years. The returns for 1922 were actually the highest recorded since 1907. Between 1907-12 the number of deaths fluctuated from 1,950 to 2,200. From 1914-17, however, rapid movements set in, the deaths falling to 1,539 in 1917, a drop of 30 per cent. in four years. Then came the terrible series of epidemics of influenza. As I pointed out, at this time the disease, associated as it is with grave pulmonary complications, not only weakens the power of general resistance, but causes local damage to the respiratory system. Hence, persons already infected with tuberculosis readily succumb, latent infections light up, too, and fresh infections tend to occur more easily. The small but definite drop in the mortality from tubercle is, in my opinion, a clear indication that the effects of influenza on the public health have at length smouldered out.

This is not nearly so marked as one would expect in view of the prevalence of respiratory diseases in the cold season. In January the mortality rate was 2·5 per thousand. A temporary drop to 1·9 per thousand in February was followed by a recovery to 2·2 per thousand in March. The mortality was almost stationary in April and then suddenly rose to 2·8 per thousand in May. This was the highest rate recorded during the year. It then fell with equal rapidity to 2·1 per thousand in June, only to rise again to 2·5 per thousand in August. During September and October it varied from 2·3 to 2·4 per thousand, again declined to 2·1 per thousand in November and finally rose to 2·4 in December.

As in previous years, nearly the whole of the mortality from tuberculosis was due to pulmonary tuberculosis, this variety of the disease accounting for 1,967 deaths out of 2,089, or 94·2 per cent. of the total mortality from tuberculosis. There were only 122 deaths recorded as due to other forms of tuberculosis, of which 97 were from abdominal tuberculosis and 25 from tuberculosis of other organs. The extremely small proportion of all other forms of tubercle, i.e., tuberculosis of bones, joints and glands is, of course, due to the rarity of bovine tuberculosis in Bengal.

(N.B.—A careful examination of apparently healthy pigs will frequently reveal terbercular glands.)

The absence of bovine tuberculosis may not, however, be an altogether unmixed blessing.

It is so frequently the case that an absence or rarity of bovine tuberculosis co-exists with a very acute type of disease in man, that it is difficult to avoid the conclusion that the two phenomena are related. There can be no question that pulmonary tuberculosis in Calcutta runs a very rapid course. It is almost certain that the great majority of Indian patients die within a year of their first symptoms. This appears to be definitely related to the fact that, whereas only 2·3 per cent. of Indians examined post-mortem show signs of old tuberculosis infection, about 85 per cent. of cadavers examined in European countries contain such lesions.

In other words, minor infections, particularly those covered by tubercular milk, which appear to lead to the acquisition of resistance to acute pulmonary tuberculosis, are extremely rare in India. If these deductions are correct, a trial of pasteurized tubercular milk as a preventive seems indicated.

With bovine tuberculosis practically eliminated, the spread of tuberculosis in Calcutta is clearly from man to man through the agency of sputum. This is obvious to anyone conversant with the habits of the people. I allude, of course, to the very dangerous and objectionable habit of promiscuous expectoration so freely indulged in by all classes.

The causes of tuberculosis in Calcutta have been enumerated so often in these reports, and the progress made towards eliminating them is so slow, that one almost despairs of this veritable "white-plague" ever being brought under control. The chief causes are: (1) Insanitary housing conditions, with the evils of want of fresh air and sunlight intensified by overcrowding, and the retention of the purdah system in a densely populated city. (2) Ignorance and poverty, the former responsible for promiscuous spitting, the latter for under-feeding and bad housing.

The death-rate amongst Mahomedans was 2·8 per thousand as compared with 2·1 amongst Hindus. The difference is less marked than last year, when the rates were 3·2 and 2·2 per thousand respectively. Amongst Indian Christians it was 2·8, and amongst non-Asiatics and Anglo-Indians 2·6 per thousand, but these rates are calculated on a very small number of cases.

The saddest feature of the return is the high mortality rates amongst girls and young women.

Between the ages of 15 *and* 20 *years for every boy that dies of tuberculosis five girls die. What is the reason for this truly appalling state of affairs? Well, to put it brutally, these girls were suffocated behind the purdah.* It is, I am convinced, the retention of the purdah system in the densely populated gullies of a congested city that dooms so many young girls to an early death from tuberculosis. In less densely populated areas, where detached houses with compounds are possible, the purdah system could be adhered to without seriously affecting the health of the inmates of the zenana.

In a great city it is difficult to secure absolute privacy without shutting out light and air, as houses in narrow lanes and gullies are almost certain to be overlooked. Consequently, the zenana is usually situated in the inner portion of the house, ill-lighted and ill-ventilated, but effectually screened from the observation. Another very important factor in the ætiology of tuberculosis amongst girls and young women is early marriage, which subjects immature females to the strain of repeated pregnancies and prolonged periods of lactation. Lastly, I would again draw attention to the many thousands of cases of tuberculosis always present in Calcutta. This is apt to be overlooked, as these reports deal almost exclusively with deaths. At a very modest estimate, assuming that there are four or five living cases for each death registered, there are probably about 10,000 cases of tuberculosis in the city at any given time. In the great majority of cases no precautions are taken against the spread of infection. To speak plainly, thousands of consumptives are constantly spitting all over the place. Can one wonder at the prevalence of the white plague in Calcutta? An anti-tuberculosis scheme which included the appointment of a tuberculosis officer with eight assistant medical officers (for systematic house-to-house visiting), a dispensary and a publicity bureau has been approved by the health committee. Unfortunately, it could not be proceeded with owing to want of funds.

Respiratory Diseases.

After steadily dropping for three years, there has been a slight rise in the mortality from respiratory disease this year, the number of deaths being 6,124, or 6·7 per thousand, as compared with 5,814, or 6·5 per thousand, last year. Although slightly higher than last year, the returns for both 1922 and 1923 are much lower than those of 1918 to 1921. They are still, however, considerably above the pre-influenza average.

Several diseases are grouped under this heading, i.e., acute bronchitis, chronic bronchitis, broncho-pneumonia and pneumonia.

A slight increase in the number of deaths from acute bronchitis is compensated for by a decrease in the deaths from chronic bronchitis. Both pneumonia and broncho-pneumonia were slightly more prevalent, but the difference is small. The mortality from pneumonia is still very high, almost double the pre-influenza figure. Apparently a certain amount of influenza with pneumonia is being registered under this head.

The seasonal prevalence was much more normal this year, the highest mortality from respiratory diseases occurring, as in pre-influenza years, in January and December. Last year, the maximum death-rate occurred in March. This was obviously due to the inclusion of undiagnosed influenza. This year a similar but less marked rise also occurred in March, probably due to the same cause. In January the maximum mortality, 8·6 per thousand, occurred. A temporary fall to 6·5 per thousand in February was followed in March by a rise to 7·5 per thousand, the influenzal rise referred to above. It then fluctuated between 5·5 and 5·7 per thousand during April-July. In August it again rose, reaching 6·9 per thousand. After remaining at 6·4 per thousand during September and October the cold weather rise occurred, the mortality being 7·7 per thousand in November and 8·2 per thousand in December.

As in the case of tuberculosis, these diseases were much more prevalent in District III (death-rate 9·4 per thousand). In Districts I and II the death-rates were slightly below, in District IV slightly above that for the city (6·7 per thousand).

The two " black lists " correspond very closely. In both cases Hastings has been excluded, the high rate there being calculated on a comparatively small number of deaths. The manner in which suburban wards with large bustees are picked out year after year is very suggestive. The poor bustees dweller, ill-clad and poorly-fed, living in a damp hut, with mud floor and mud-plastered walls appears to be particularly susceptible to respiratory diseases. This is particularly the case in those areas which are not adequately drained and liable to flooding during the rains. Overcrowding and want of fresh air are also potent factors in the causation of respiratory disease. During the cold season an early morning visit to a bustee reveals every hut hermetically sealed, with filthy rags stuffed into every opening that cannot be closed otherwise.

As to age incidence, acute bronchitis is one of the principal causes of death amongst infants and young children. Out of 1,784 deaths from acute bronchitis, 1,401, or 78 per cent., occurred amongst infants, and 365, or 20 per cent., amongst children under five years of age.

Chronic bronchitis.—This is, of course, a disease from which old people suffer chiefly. Out of 1,281 deaths, no fewer than 775, or 60 per cent., occurred amongst persons 60 years of age and over.

Pneumonia.—The most susceptible age-periods appear to be 20-30 years and 30-40 years, 656 deaths out of a total of 1,748, or 37 per cent., occurring at these ages.

As a group, respiratory diseases were more prevalent amongst females than amongst males, the death-rates being 8·5 and 5·9 per thousand respectively. In the case of pneumonia, however, the exact opposite is found, the mortality amongst males being higher than amongst females.

The incidence of these diseases varies considerably amongst different sections of the community. The highest death-rate, 9·0 per thousand, was recorded amongst Mahomedans; the lowest, 3·9 per thousand, amongst non-Asiatics and Anglo-Indians. Amonst Hindus it was 6·2 and amongst Indian Christians 5·0 per thousand.

Influenza.

Only 371 deaths, equivalent to a death-rate of ·40 per thousand, were registered this year, a marked

decline compared with 1922, when 688 deaths, or ·75 per thousand, were recorded. As already noted, a certain proportion of cases are probably returned under the headings "respiratory diseases," "other fevers," &c., but, as the same error occurs every year, the annual returns are strictly comparable. From this point of view the steady decline from 4,115 deaths in 1918 to 371 deaths in 1923 is satisfactory, particularly as the mild recrudescence this year never assumed epidemic form.

The highest mortality, ·75 per thousand, occurred in January, and the lowest, ·18 per thousand, in June. From July-September it fluctuated between ·40 and ·50 and then declined during the last quarter of the year to ·30 per thousand. A very slight and evanescent rise in March occurred, but there was nothing like an epidemic.

The death-rate amongst Hindus was more than double that amongst Mahomedans, the mortality rates being ·48 and ·23 per thousand, respectively. As only four deaths were registered amongst the rest of the population it is useless giving death-rates. Males with a death-rate of ·47 per thousand were nearly twice as susceptible as females (death-rate ·26 per thousand). The highest mortality rates occurred during the age-periods 50-60 years and 60 years and over.

Kala-azar.

The mortality from kala-azar, which has been increasing steadily for several years, shows a sudden and very marked rise this year. The number of deaths recorded as due to kala-azar was no less than 501, or ·55 per thousand. This is nearly double the number registered last year (287, or ·31 per thousand) and almost five times the number recorded in 1919 (109, or ·12 per thousand). A very large proportion (217 cases, or 43·3 per cent. of the total) of the cases of kala-azar occurring in Calcutta are imported. Making every allowance for these, there seems no doubt that the number of indigenous cases is increasing, or, in other words, kala-azar is becoming more prevalent in Calcutta.

Broadly speaking, more deaths from kala-azar occurred in the latter half of the year, the highest mortality (·79 per thousand) occurring in September and the lowest in February (·31 per thousand). The increased prevalence after the rains rather suggest the inclusion of a certain number of cases of chronic malaria (quartan) in which great enlargement of the spleen occurs. On the other hand, as already noted, kala-azar is sometimes returned as malaria.

The incidence of kala-azar amongst different sections of the community is extremely interesting and in marked contrast to that of malaria and others fevers.

The relatively high death-rates amongst Indian Christians and Anglo-Indians for several years in succession appears to indicate either increased susceptibility or some special ætiological factor. As nothing definite is known as to the mode of spread, although it seems highly probably that some insect is the vector, all that can be done in the way of prevention is to provide facilities for the early diagnosis and treatment of cases. Every case cured is a one source of infection the less. In view of the remarkable cures affected by the intravenous injection of salts of antimony, it has been decided to open a large number of centres for treatment all over Calcutta. The scheme is now under consideration by the Public Health Standing Committee.

Dengue.

A severe and widespread epidemic of dengue swept through the city during the months of August, September and October. All classes of the community were affected, and it is estimated that from 30 to 40 per cent. of the population were attacked. In a city with a population of over 900,000 this means that there were about 300,000 cases. Only a few months before the onset of the epidemic the mosquito brigades were disbanded, in spite of my protest. Possibly the outbreak of dengue shortly after this retrograde step was only a coincidence. Whether there was any connection between the two events or not there can be no question that the health department were severely handicapped in dealing with the outbreak. A few inspectors and coolies were grudgingly sanctioned, but there was no time to organize the anti-mosquito work properly. Had the mosquito brigades been retained it would have been a simple matter to extend and enlarge an existing organization working under trained inspectors, and although the epidemic could not have been prevented, its ravages might, I think, have been checked to a certain extent. The epidemic appears to have started early in August. The first cases were reported from Kidderpore, but infection spread so rapidly and cases were reported from all parts of the city at such short intervals that it is almost impossible to trace the outbreak to any particular area. It reached its height in September, and though still very prevalent in October was obviously on the decline. Altogether 31 deaths were attributed to dengue. Of these 9 occurred in August, 14 in September and 8 in October. Assuming that my estimate of the number of cases is approximately correct, this is equivalent to a mortality rate of ·1 per thousand. Megaw (Dengue sand fly-fever problem I.M.G., September, 1923) gives a mortality range for dengue of from 0·1 per cent., the average being about ·05 per cent., or ·5 per thousand. The death-rate given above, though lower than the average, is within the range given by Megaw and is, I think, evidence of the correctness of the estimate made of the number of attacks.

Every possible clinical variety of the disease was seen during this epidemic. Mild cases with a few days fever and no other symptoms. Typical 3-day fever cases with severe pains, rash and secondary fever phase. Characteristic 7-day fever cases with and without pains, rash, &c. A remarkable feature of this outbreak was the number of cases in which severe pain in the vicinity of one or more joints persisted for weeks and even months. I give below

a very valuable and suggestive questionnaire issued by Lieut.-Col. Megaw, I.M.S., Director, School of Tropical Medicine, together with the answers submitted by the Health Department. These were based on roughly 2,000 cases seen by the M.O.'s of Dispensaries and the Assistant Sanitary Officers.

Questions regarding Dengue.

(1) How many cases have you seen?—Nearly 2,000.

(2) In your experience, have any races or classes been specially affected?—No.

(3) In your opinion, what percentage of the total population has suffered from the disease?—About 40 per cent.

(4) What proportion of your cases lasted—(*a*) Less than three days altogether?—30 per cent. (*b*) Less than three days, with a secondary fever about the fifth to the seventh day?—40 per cent. (*c*) Continuously for five to seven days?—25 per cent. (*d*) Longer than seven days?—5 per cent. to 10 per cent.

(5) In what proportion of the cases was a secondary rash seen (viz., a rash after the second day)?—In over 50 per cent.

(6) In what proportion of the cases was a relapse noticed?—In about 10 per cent.

(7) How long after the original attack did the relapses occur?—Please state (*a*) the shortest period—3 days. (*b*) the longest period—1 month. (*c*) the average period—1 week.

(8) In what proportion of cases did pains persist for a considerable time after the fall of the temperature?—30 per cent.

(9) Did you observe any features of the disease in which it differed from the ordinary dengue as described in the text-books? If so, please specify, giving figures to show the frequency of the feature referred to.—No.

(10) Did you observe any special complications of the disease? Please state these and the number of cases in which each occurred.—Acute intestinal trouble, dysenteric in character; 15 to 20 per cent. of cases had diarrhœa with malaria in a few instances. Arthritis noticed in 10 per cent. of cases. Enlarged lymphatic glands common. Recurrence of chronic ailments, such as rheumatism, asthma, pyorrhœa, &c.

(11) Did you observe any special sequelæ besides after-pains and debility? Please give details, stating the number of cases in which each occurred.—Œdema of feet, arthritis of large joints. Pharyngitis with enlarged tonsils. General glandular enlargement.

(12) In what proportion of the cases was swelling of the feet noticed after the disease?—In a few cases only.

(13) Did you observe any features in the spread of the disease which are opposed to the view that it is mosquito-borne?—No.

Epidemic Dropsy.

Four groups of cases of epidemic dropsy, three in Calcutta and one in Manicktola, occurred during the year.

Researches into the cause of epidemic dropsy are being carried on at the Tropical School of Medicine. Some very remarkable results have already been obtained and there is every reason to believe that Major Acton and his colleagues, working under Lieut.-Col. Megaw, will shortly solve the problem. The Health Department is working in close co-operation with the Tropical School, investigating local outbreaks, tracing the rice supply, securing samples of rice, examining the condition of storage, &c. At Lieut.-Col. Megaw's instance, a joint conference was held on September 21 at the Tropical School. The following is a brief summary of the conclusions arrived at:—

(1) Epidemic dropsy is undoubtedly caused by eating rice. It has never been known to occur amongst persons who do not eat rice.

(2) Recent experimental work at the Tropical School has shown that rice that has been stored for some time under certain conditions of temperature and moisture is attacked by a fungus or bacterium, and a toxin is formed which, when extracted and injected into animals, is capable of producing all the symptoms of the disease.

(3) The actual organism has not yet been isolated.

(4) It is not possible at this stage to assert that a particular sample of rice will cause epidemic dropsy without elaborate pharmacological tests on animals. That is to say, the seizure and destruction of rice suspected of causing epidemic dropsy as unfit for human food is hardly practicable at this stage.

(5) On the first appearance of symptoms of the disease absolute stoppage of rice and a mixed diet rich in vitamines, e.g., fresh milk, eggs, ghee, butter, fresh vegetables, fish, meat, &c., not only prevents the further development of the disease, but effects a perfect cure.

(6) As a preventive measure the use of freshly prepared rice is strongly recommended.

(7) An illustrated poster with the main facts given in simple language, has been drawn by Lieut.-Col. Megaw. It was decided that this should be published and circulated by the Health Department, particularly in markets and infected localities.

VACCINATION.

There were only 157 deaths from small-pox in 1923, against 450 in the previous year. This low mortality accounts for the heavy decrease in the total number of vaccinations done during the year under review, when altogether 48,062 persons were vaccinated, whereas the number of vaccinations was almost twice as much in the preceding year. As a result of long experience, it has been found that in a non-epidemic year it is practically impossible to push on vaccination vigorously, and the obvious reason is the stolid indifference of the people, who are not alive to the importance of vaccination as the only preventive measure against an attack of this terrible disease. Out of this total number (48,062), 17,223 were primary and 30,839 were re-vaccinations.

Colonial Medical Reports.—No. 184.—Calcutta (*contd.*).

SPECIAL WORK DONE AT THE LABORATORY.

Bacteriological.

Anti-typhoid Inoculations.—Towards the end of December, 1922, shortly after His Royal Highness the Prince of Wales left Calcutta, an explosive outbreak of typhoid fever occurred amongst the European population of the town and a few highly respectable gentlemen and ladies succumbed to it. Several suffered from it. Bacteriological examination of the blood of some of them was made in this laboratory, and positive Widal reaction to *Bacillus paratyphosus* was found in most of them. Announcement was made in the local newspapers inviting the public to have free prophylactic inoculations at the municipal laboratory, and a ready response was received from the European section. Scores of ladies and gentlemen visited the laboratory daily for the inoculation. Besides, in the case of public institutions like schools, colleges, offices and workshops, we used to visit them and gave them the inoculations at their own places. During January and part of February, altogether about 800 inoculations were performed and the epidemic was promptly controlled. Supply of lymph was obtained from the Government Laboratory at Kasauli. Thanks are due to the authorities there for their kindly supplying us with fresh vaccine promptly whenever a requisition was made. It is a matter of gratification to note that there was not a single case reported of having any untoward symptoms from any of the ladies or gentlemen who were inoculated by us with this vaccine.

Animal Vaccine Depot.

Throughout the year a good supply of glycerinated lymph was maintained at the depot and the stock in hand was more than double the quantity actually required.

The reserve stock of glycerinated vaccine lymph in hand on January 1, 1922, in our refrigerator was 108 large test-tubes full, and during the year 68 test-tubes were manufactured, which made a total of 176 test-tubes of vaccine virus. Each test-tube containing lymph sufficient to charge about 300 capillary tubes, three persons can be vaccinated with one capillary tube of lymph, so our reserve stock was sufficient for over 184,800 vaccinations.

At the commencement of the year there were 16 calves available for vaccination and 75 calves were hired during the year. Of these, 56 were utilized for the manufacture of lymph, 5 were returned as unfit for vaccination, leaving 14 calves available on December 31, 1923. So in all 72 (16 and 56) calves were vaccinated during the year; of these, 16 failed to yield vesicle pulp of good quality and the remaining 56 calves yielded 11,883 grains of vesicle pulp of excellent quality, which, being triturated with diluted glycerine, made 83,181 grains of glycerinated lymph. The average yield of vesicle pulp works out at 212·1 grains per calf. As usual, only healthy female calves with light coloured skin were selected for vaccination, as pigment is the sign of a coarse, tough skin and the vesicles produced are inferior to those on a soft, tender, non-pigmented skin. Male calves are not used for vaccination as they are apt to foul the vaccinated area of the abdomen with urine, &c. As a result of careful selection, there was no outbreak of "rinder pest" and foot-and-mouth disease amongst the calves, though the contractor supplied from the different bazaars.

The supply of calves is obtained from a contractor on a hire system. After vaccination, when the incisions are healed, the calves are returned to the contractor. After arrival the calves are kept under quarantine for ten days and daily carefully examined and any calf showing the slightest signs of disease is at once returned to the calf contractor.

From the quarantine shed healthy calves are removed to the tuberculin shed inside the depot and are tested against tuberculosis prior to vaccination. After allowing about a fortnight for recovery they are then vaccinated. During the interval they are carefully fed and attended to in order to get them into good condition, as calves in poor condition do not give vesicle pulp of good quality and the yield is scanty. In addition to the tuberculin test, the carcasses of all the calves are examined and certified free from tuberculosis by the veterinary assistant, Tangra.

The amount of glycerinated lymph issued from the depot to the public vaccination station of the city during the year was 31,825 capillary tubes, as compared with 52,141 in the previous year. Altogether 39,706 capillary tubes of glycerinated lymph were sent out from the depot during the year, against 64,341 in the previous year. This increase of 1923 was due to a mild outbreak of small-pox in District I. The total number of deaths from small-pox recorded during the year was 157, against 450 of the previous year. This being the third non-epidemic year, the people of the city did not care much to be vaccinated and so only 39,706 vaccine tubes had to be issued from the depot for vaccinations.

Only ripe lymph thoroughly cured by glycerine was sent out from the depot. The lymph of the depot maintained its customary high quality, which was tested by diverse trials at the depot prior to distribution. The bacteriological examination of the lymph at the municipal laboratory prior to distribution proved it as entirely free from pathogenic micro-organisms. Above all, the results of thousands of vaccinations performed every year afforded the best possible experimental proof of its potency and purity.

Analyst's Report on the Results of the Examination of River Water near points of Discharge of Septic Tank Effluents in February, 1923.

In July, 1922, the General Committee ordered an investigation into the quality of river water near Pulta Intake at different seasons of the year, with a view to finding out what effects, if any, are discernible by the discharge of effluents from various

sources into the river. In accordance with the above, a survey of the river was made in the month of August last, when 100 samples were taken and analysed. As a result of that investigation certain conclusions were tentatively drawn, which were embodied in a report and submitted to the General Committee. Another investigation on similar lines was started in February last, in which 107 samples of river water and effluents were taken from the river between Khardah and Samnagore. As before, the samples were collected in sets of three; the shore in the vicinity of discharge pipe of septic tank effluents, midstream, and the opposite shore. Samples were also collected from the Pulta Intake and also of the effluents from some of the septic tanks. For purposes of comparative study, the results have been classified into four groups, viz., (1) midstream, where the river is comparatively free from the influence of pollution entering from the shores; (2) shore or bathing ghat within 400 feet from the places where the effluents are discharged; (3) river water close to open drains; (4) effluents of groups of septic tanks.

The following general conclusions may be made from the results recorded therein:

(1) As noticed in August last, the midstream water is purer than water at either shore, although the February samples show distinct deterioration in quality, inasmuch as 32 per cent. of the samples showed 10 fæcal bacilli per c.c., compared with only 12 per cent. in August, and 4 per cent. showed 1,000 fæcal bacilli per c.c., whereas none of them had this number in August.

(2) The shore samples were decidedly inferior in quality to the midstream ones, as observed in August last. At the same time they were inferior in quality to the August samples.

(3) The Pulta intake water is almost as pure as midstream water, though the actual quality of the February samples is inferior to the August samples, inasmuch as in February 12·5 per cent. samples showed as many as 100 fæcal bacilli per c.c., whereas in August none of the samples reached this number.

(4) The results of examination of the septic tank effluents do not indicate any sign of improvement and are, if at all, only worse than the August samples. Of the February samples, 33 per cent. showed 1,000,000 fæcal bacilli per c.c.—a condition identical with that obtained from crude human fæces.

(5) The results of the mixture of effluents and river water, as in Khardah Khal, Titagur Khal and Ichapur Khal, are also worse than those obtained in August last.

It appears from the above that in the month of February, when the volume of water in the river is considerably less than in the rainy months of August, the amount of pollution is proportionately greater, the dilution being less.

The health officer reports as follows: Although the number of samples examined is small, I entirely agree with the conclusions drawn by the analyst. In investigations of this sort the method of taking samples and the technique employed are of great importance. In order to satisfy myself on these points I accompanied the analyst on one of his inspections. In all cases fair average samples without obvious gross pollution were taken. Most important of all dilutions and inoculation of media were rapidly carried out on the boat, thus avoiding the errors due to delay in sending samples to the laboratory.

The general deterioration in the quality of the river water, both midstream and in-shore, to which the analyst refers, was anticipated from our experience at Pulta. As he points out, it is almost certainly due to the diminished volume of water in the river. The most unsatisfactory feature of the report is the extremely bad results obtained from the examination of mill effluents. True, the number is small, but these results clearly show that the chlorination of septic tank effluents is not being carried out effectively. At Rishra a most interesting sight was seen, viz., effluent and almost boiling water being discharged into the river side by side. If chlorination is so difficult to enforce some system of sterilization by waste boiler water or steam seems worth a trial. On the opposite shore the contrast between the Titagur Khal, reeking of chlorine and the foul Khardah Khal only a few hundred yards away, was very striking. If a portion of the former could be diverted into the latter it would improve it considerably. In the letter of May 19, from the Secretary to the Government of Bengal, as the dates of collection of the samples referred to are not given, one is hardly in a position to compare results. As already noted above, our results appear to indicate that, save for a small percentage of cases, no attempt has been made to chlorinate the effluents. As regards the Kharda Khal Government may be requested to inform us of the measures taken by the local municipalities to put a stop to the gross fæcal pollution of this Khal. In the enclosure to the letter it is stated that improved chlorinating apparatus has been installed in thirty mills at the instance of the public health department and that the director of public health has arranged for the regular bacteriological examination of ninety samples of effluents every month.

The following conclusions may be drawn from the foregoing results:

(1) The midstream water is purer than water at either shore.

(2) The water near the shores shows marked signs of fæcal pollution.

(3) No marked improvement in the quality of shore water is evident since the last reports were submitted.

(4) The results of examination of septic tank effluents do not indicate that any appreciable improvement has been effected.

In the Government letter No. 50 T.P.H., dated May 10, 1923, it has been stated that an increased number of effluents are being sterilized before being discharged into the river. It seems probable that the factories from which my samples have been collected, have either not adopted the proper sterilization method or are not working it continuously.

In fact, my samples were confined to eight to ten factories situated on the river bank between Khardah and Titagur.

Even admitting that all of these factories adopt strict sterilization methods, still the continuous efficient working of these plants cannot be guaranteed. So, in view of the fact that, as years go on, the number of septic tanks on the river side will undoubtedly be on the increase and that pollution from these sources could not be avoided, even with the best of intentions, I would strongly recommend the advisability of considering the question of erecting a chlorinating plant at Pulta, not for working it throughout the year, but only at such times when its use would be considered necessary.

I would also urge the consideration of an Act for the Prevention of River Pollution on the same lines as the River Pollution Acts of England and America.

Colonial Medical Reports.—No. 185.—Trinidad and Tobago.

ADMINISTRATION REPORT OF THE SURGEON-GENERAL FOR THE YEAR 1924.

COLONIAL HOSPITAL, 1924.

Extern-Maternity Department.—305 women were delivered at their own homes during the year and 3,470 visits were paid by our nurse-midwives. Judging from the frequent calls made on our nurse-midwives, it is clear that their attendance is greatly appreciated by the poorer classes, and worked as it is in conjunction with our maternity ward it provides a very efficient maternity service which is bound to be of great benefit to mothers and infants alike.

Ambulance.—The ambulance has done good work during the year, but with the ever increasing work in this department it will soon become necessary to have another ambulance attached to the hospital so as to ensure a constant uninterrupted service for special cases. Perhaps some generous donor might thus help to carry on the good work for which we are indebted to the generosity of Mr. J. W. Stephens, the donor of No. 1 ambulance. We have to be thankful to Mrs. Arthur Wight for two very handsome surgical beds presented by her to the Colonial Hospital, which have greatly added to the comfort of patients and their attendant nurses.

A trolley with canopy for sunning bed-ridden patients has been presented by Mrs. Randolph Rust and a gramophone for the tuberculosis ward by Mrs. Lack. We are also grateful to many other friends of the institution who have regularly during the year provided small comforts for the patients in the shape of oranges and limes for the general wards and sweets and toys for the children. It is gratifying to see the general public thus taking an increased interest in our institution, which is only too grateful for any favours received.

In conclusion I wish to point out that outside of purely technical work the administration of a large institution like the Colonial Hospital with its many and increasing ramifications (such as Extern maternity service, ambulance service, health office, and venereal clinic) is a large undertaking which requires the services of a whole-time manager or secretary-manager, instead of being vested in the resident surgeon, who should be too absorbed in his own professional duties to be able to go into small details of discipline and administration.

Water Supply and Sanitary Arrangements.—The water supply has been good during the year. A new hot water system for the operation room, maternity and acute wards has been devised, and will, I hope, soon be established.

The sanitary arrangements are good and up to date.

Diet.—The dietary has been satisfactory, the new kitchen range has effected a much needed improvement in the cooking.

Accommodation.—The daily average of patients has been exactly the same as the authorized number of beds, namely, 340. This does not mean that there has been no overcrowding—at certain seasons of the year the number of admissions cannot be accommodated, and in spite of all our efforts the chronic wards become uncomfortably congested. This is due to the insufficient accommodation at the House of Refuge necessitating our keeping at hospital numerous cases which should be accommodated there. I have on frequent occasions called attention to this, but with no improvement; the House of Refuge, which is in reality a house for the aged or disabled poor and therefore entirely restricted to chronic cases, is never called upon to make room for an extra inmate, yet the Colonial Hospital, an institution primarily meant for acute cases, must admit destitute poor cases even though the floor beds in a ward make circulation therein a matter of difficulty. This, I think, ought to be rectified, and would ultimately prove economical, the cost per head of a patient in the Colonial Hospital being considerably in excess of the cost of a patient at the House of Refuge.

The greatest number of patients in hospital on any one day was 371, the smallest number 302. The chief diseases treated were: Enteric fever, malarial fever, gonorrhœa and syphilis, pulmonary tuberculosis, chronic nephritis, enlarged tonsils and adenoids, ulcers, ankylostomiasis, hernia, pneumonia, bronchitis, diarrhœa and dysentery.

There has been a big increase of enteric fever with a comparatively low mortality.

Malarial fever also shows a marked increase, the large majority of these cases come in from the country districts; very few originating in the city of

Port-of-Spain. On the other hand, there has been an appreciable fall in pulmonary and intestinal diseases, no doubt due to the more seasonable weather prevailing.

The total number of cases treated as in-patients during the year was 5,999 and the number of deaths 867. If cases, both medical and surgical, were admitted in an earlier stage of their disease the case mortality of the hospital would be very much lower than at present, and the help of the general practitioner and also of the public would be much appreciated by the hospital staff in this matter.

The number of casualties treated in the surgery, exclusive of in-patients, was 2,991.

Surgical Operations.—There were 1,703 operations performed during the year, with 50 deaths.

San Fernando Hospital, 1924.

Water, &c.—The water supply was adequate during the latter half of the year, but some difficulty was experienced during the dry season. The pail system is in use.

Diet.—The diet is satisfactory and also the cooking. The supply of fresh milk was increased and the greater part of this is now obtained from the Government Farm. A few additions to the diets were authorized during the year and much appreciated by the patients.

Accommodation.—The hospital contains 153 beds, of which 20 are reserved for tuberculosis cases, 7 for maternity cases, and 3 for private room patients. 3,311 patients were treated in the wards. 111 patients were treated in the maternity ward. 93 patients were attended to by the Extern midwife and 915 visits made. 975 patients were treated in the surgery exclusive of patients suffering from diseases of the eye, ear, nose and throat, and diseases of women, of which unfortunately no record was kept.

The Venereal Clinic was opened daily for the free treatment of venereal diseases.

The following diseases were treated: Syphilis, gonorrhœa, granuloma, and yaws.

The chief diseases treated in hospital were: Ankylostomiasis, syphilis, malaria, dysentery, chronic nephritis, bronchitis, phthisis, pneumonia and enteric fever.

Lunatic Asylum, 1924.

Admissions, Discharges, Deaths.—Among the admissions, which were fewer than in the preceding year, cases of mania greatly exceeded any other form of mental disorder. A welcome feature was the larger number who were brought under institutional treatment at an early stage of their illness, affording a hopeful prospect of useful recovery.

Fifteen (10 per cent.) of the admissions made a good recovery and were discharged before the end of the year. The recovery rate was 36 per cent., as compared with 27 per cent. in the preceding year. In spite of the difficulty of obtaining reliable histories, hereditary instability was clearly the most frequent predisposing cause.

The deaths were fewer than in 1923, and included 12 from tuberculosis, the bugbear of asylums. Enteric fever caused five deaths. The three remaining cases of general paralysis of the insane, a rare form of mental disease in this asylum, died during the year. The percentage of deaths on the average number resident was 12·3.

Accommodation.—There were at the end of the year under review 46 vacancies for males and 30 for females. The total number under treatment was 800, and the average number resident 649.

Buildings, Water Supply.—The buildings were maintained in good order. The water supply was ample.

Employment.—The usual high percentage of inmates employed was well maintained, and work of a considerable economic value was accomplished throughout the institution. The value of the produce from the grounds was not up to the average owing to unfavourable weather during the greater part of the year.

Health of the Institution.—Typhoid fever continued to appear sporadically among the inmates, six females and three males being affected. No fresh case has occurred since October. For some years past the incidence of dysentery has been steadily declining, and the few cases during the year were of a particularly mild type.

Staff.—The conduct of the staff was generally good, in spite of the resignation and retirement of several of the senior employees having greatly increased the proportion of probationers on the staff.

Leper Asylum, Cocorite.

(*A*). The general accommodation is ample and consists of one large building, two churches, one day room, twelve wards, one laundry, two linen rooms, one mortuary and one incinerator. The staff consists of one resident superintendent, one dispenser, 17 nurses, one steward and 23 employees. The conduct in general of the staff has been satisfactory, and I should like to add that the staff as a whole deserve not only the gratitude of the inmates but of the public in general for the devotion, self-sacrifice and untiring energy towards the care and welfare of the inmates and not less of the institution under their care and management. Quarters are provided for the resident superintendent, the sisters of the nursing staff, and the steward.

(*B*). The buildings are not in very good condition —the institution as a whole needs thorough repair and repainting.

(*C*). The water supply is ample and of good quality. The drainage is satisfactory and the incinerator works satisfactorily.

(*D*). The diet is good.

(*E*). Twelve wards are provided for the accommodation of patients—six male and six female. Their condition is referred to in paragraph *B*.

(*F*). The chief diseases treated are leprosy in its various forms, with complications of tuberculosis, hookworm, and general systemic ailments.

Colonial Medical Reports.—No. 186.—Bengal.

MALARIA AND AGRICULTURE IN BENGAL: HOW TO REDUCE MALARIA IN BENGAL BY IRRIGATION.

By CHAS. A. BENTLEY, M.B., D.P.H., D.T.M.& H., K.H.G., F.S.S.

Director of Public Health, Bengal.

Malaria and Agriculture.

A close association has always been recognized between malaria and agricultural conditions, and it has long been known that a greatly increased prevalence of the disease almost invariably accompanies the decay of agriculture and the decline of cultivation.

The cultivation of the soil in relation to malaria is, therefore, of overwhelming importance, and with good reason, for the question of rural malaria is so closely bound up with that of agriculture that the one cannot be properly understood without some knowledge of the other. Moreover, there are grounds for believing that the mitigation and prevention of malaria in the rural districts of Bengal, a problem for which no adequate solution has yet been suggested, may eventually be secured by measures designed as much for preserving or restoring agricultural prosperity as for directly dealing with malaria.

In Bengal, where the bulk of the people are dependent upon agriculture, low death-rates and good health accompany agricultural prosperity, and high mortality and bad health on the contrary are as clearly associated with evidence of agricultural deterioration

For many years past, the growth of the population in Western and Central Bengal has undergone a serious check owing to diminished birth-rates and excessive mortality. The factors mainly responsible for this condition are malaria and economic stress resulting from agricultural decline. These factors are known to be specially destructive of child life, and the proportion of children under ten in the different natural divisions reflects their influence very clearly in the case of both Western and Central Bengal.

The lower death-rate, higher birth-rate and more rapid growth of population in Eastern Bengal are due to the relatively better heath and greater agricultural prosperity of this natural division.

The lessened incidence of malaria in Eastern Bengal is the main cause of its better health. Malarial fever is at least three times more prevalent in Northern Bengal, four times more prevalent in Central Bengal and five times more prevalent than in Western Bengal.

As regards agricultural prosperity, we find that during the decade 1901-1911, agricultural conditions were much more favourable in Eastern Bengal than elsewhere. For example, whereas the outturn of the principal food crops fell short of the normal by 21·8 per cent. in Western Bengal, 21 per cent. in Central Bengal and 12 per cent. in Northern Bengal, the deficiency in Eastern Bengal was only 7·2 per cent. Land was also more widely cultivated in Eastern Bengal and the proportion of fallows very much less than elsewhere.

The factors which mainly determine the outturn of crops, thus governing the agricultural prosperity of different areas in Bengal, are: (1) the relative fertility of the soil, (2) adequate and seasonal rainfall, and (3) liability to enriching inundations with silt-bearing river water. Two of these factors—rainfall and inundations—also exert an important influence upon malaria, heavy rainfall and wiwdespread inundation of the land surface tending to check the breeding of anopheles mosquitoes, whereas short rainfall and scanty inundations favour their increase. Hence the relative prevalence of malaria is largely influenced by the same conditions which determine a good or a bad harvest.

The soil in Eastern Bengal is so much more fertile than that in the other natural divisions that land rarely needs to lie fallow.

Eastern Bengal.—The causes both of the perennial fruitfulness of Eastern Bengal and the relative infertility of the western portion of the delta are well known. We read in the statistical account of Bengal that, "lands adjacent to rivers, or watered by them, do not require manure, but other lands do," "that low lands which are continually flooded do not require to lie fallow in order to preserve their fertility," and that in Eastern Bengal, "rotation of crops is nowhere practised, nor can it be said to be required, as by far the greater part of the arable land is each year refreshed with a new deposit of river mud." Both the *Imperial Gazetteer of India* and the various census reports point out that Eastern Bengal enjoys advantages for which it would be difficult to find a parallel in any other part of India.

"The rainfall is abundant, is usually well-distributed and is never known to fail. The land of the delta is enriched by yearly deposits of silt. The climate, the soil and the river system are all alike favourable to cultivation.

"In its course through Bengal, the Ganges rolls majestically down to the sea in a bountiful stream. . . . .Embankments are seldom required to restrain its inundations, for the alluvial deposits, which it spills over its banks year by year, affords the fields a top dressing of inexhaustible fertility. The natural overflow of the periodic inundation is sufficient to supply a soil which receives in addition a heavy rainfall, and this natural overflow is allowed to find its own lines of drainage. The plains of Eastern Bengal, watered by the Brahmaputra, yield abun-

dant crops of rice, jute and mustard, year after year, without undergoing any visible exhaustion.

"The gneissis, laterite, and old alluvial soils are alike mainly dependent upon artificial manures to maintain their fertility, whereas the recent alluvium is periodically fertilized by fresh deposits of silt from the overflowing rivers. The latter process is most active in Eastern Bengal, in the deltas of the Ganges and the Brahmaputra, whose waters possess the fertilizing properties of the Nile."

Central Bengal.—While the astonishing fruitfulness of Eastern Bengal is thus ascribed to the periodic flooding of the country, the relative impoverishment of Central Bengal is admittedly due to the cessation of the similar fertilizing inundations which that area used once to enjoy.

The Bengal census report of 1901 refers to the condition of Central Bengal in the following words:

"Central Bengal, which is bounded on the west by the Bhagirathi, on the north by the Padma, and on the east by the Madhumati, was formerly the Ganges delta, but it has been gradually raised above flood level, and the great rivers which formerly flowed through it, depositing their fertilizing silt, yielding an ample supply of wholesome drinking water, and draining it, having shrunk to insignificance. Their mouths have been silted up and their beds are often higher than the surround-country, which they are no longer able to drain. The country has become less healthy, and is far less fertile than it was formerly.

Northern Bengal.—A portion of Northern Bengal enjoys advantages similar to those which have brought prosperity to Eastern Bengal. But in the centre and the west of the division the land is too high for inundations and in Rajshahi and part of Pabna they have also practically ceased.

It may be remarked that of late years complaints have been made regarding the silting up of the rivers in Malda, and the author, when touring the district, was told by a number of cultivators that fertilizing inundations with river water are now less common than formerly.

Eastern Bengal and certain parts of Northern Bengal owe their agricultural pre-eminence to the fact that they are each year inundated by the spill waters of the great rivers, which, besides affording an ample supply of moisture for the purposes of cultivation, bring with them a rich supply of silt, which is deposited upon the surface of the country, thereby renewing its fertility, and it is the same agency which keeps these areas almost free of malaria.

Central Bengal.—Agricultural conditions in the western portions of the Gangetic delta make a very poor showing, compared with those in the east. Take the cases of Nadia, Murshidabad and Jessore; as for back as 1881 the report of the Nadia Fever Commission remarks:

"*Diminished fertility of the soil in Nadia.*—There is a consensus of opinion among Europeans and Natives that, except in the low lands used for the rice crop reaped in the cold weather, there is a distinct decrease in fertility of the soil of Nadia. Considering that no land except that used for sugar-cane and tobacco is ever manured, and that the Ganges floods, which are so fertilizing, are shut out by the embankments of the rivers, it is not to be wondered at that gradually the soil should become partially exhausted."

Even earlier than this time, the effect of diminished inundations had become apparent, as may be seen from the passage quoted below, which occurs in a letter from the indigo-planters, published in the Supplement to the *Calcutta Gazette* of 1864 in quite another connection.

"In the low rich land affected by the inundation the *raiyats* go on year after year sowing their crops without experiencing any great deterioration. On the high lands depending on the elevation of the soil, and where not enriched by annual deposits, the *raiyat* merely extracts what he can without returning anything to it in the way of manure, and consequently this soil becomes exhausted, forcing them to let the land remain fallow for one or more years."

The Effect of Embankments in causing Malaria and Agricultural Decline.

Deltas naturally free of Malaria.—Contrary to what is often assumed and even definitely stated in the older medical text-books, deltaic swamps and the so-called "bottom lands" adjacent to large rivers are as a rule comparatively healthy and naturally free from a serious amount of malaria.

The freedom from malaria enjoyed by the delta of the Nile was mentioned by Strabo over two thousand years ago. And the same author remarked of Ravenna, a city in the delta of the Po-Reno, that like Alexandria, though surrounded by swamps, it was free of marsh fever. Ravenna remained healthy for a long period. Thus Vetruvio cited it as an example of a well-situated and healthy city; and Chig quotes Marzia as praising its salubrious air while complaining of the incessant croaking of the frogs. Ultimately, however, partly as the result of natural causes and partly owing to artificial changes, Ravenna became very malarious and has remained so for many centuries. The big deltas of China are known to be comparatively non-malarious. The troops from India encamped on the muddy flats of the Peiho and Peithang rivers in 1860 enjoyed an extraordinary immunity from malaria and even those regiments which had suffered severely in India were exempt. "Even the depressed oriental race of China," says Wilson, "seems never to have had a difficulty in mastering the great problems which the necessity for the subjugation of rivers forces on civilized man; the Chinese waters have been turned to the most profitable account; their deltas seem healthy and abound with life . . Agriculture is said to be perfect." The singular immunity of certain deltas from serious malaria has been reported from many other parts of Asia.

The Great Dismal Swamp in Florida has long been considered remarkable owing to the fact that malaria is rarely or never contracted there. And although some parts of the Mississippi delta are malarious other portions of swampy littoral are reported to be

healthy. The deltas of the big rivers in South America have long been known to be relatively non-malarious. Humboldt, Bates and Galt all record the comparative freedom from malaria observable in the delta of the Amazon in contradistinction to the river valleys, some of which are appallingly unhealthy.

Malaria is absent from the pampas of the River Plate and the delta of the Parana River. Mantegazza (1858-62), confirming the previous reports of Wilson and Brunel (1842), states of the banks of the Rio-de-la-Plata that "paludal fevers are nowhere known."

The deltas of some of the large African rivers are as yet comparatively free of malaria.

Daniels records in his report to the Royal Society that he was unable to find anopheles mosquitoes in the swamps at the mouth of the Zambesi; and he mentions of a town at the mouth of the river that "Chinde now has the reputation of being a healthy place of residence." As regards the delta of the Niger, it may be mentioned that Annett, Dutton and Elliott, the members of the Malaria Expedition to Nigeria, spoke of Brass, which is in the delta, as "a comparatively healthy district."

In Sumatra, the low-lying areas along the flat banks of the Palembong river enjoy a comparative immunity from malaria fever. And the recent investigations of Terburgh show that there is little malaria at Palembong, Sourabaya, Padang and Banda. In Borneo, at Sambas, few cases of fever are to be met with in the marshy plains. Among 2,385 children examined in this situation only 78 or 3·2 per cent. showed splenic enlargement, whereas in a neighbouring hill-station 441 among 534 or 82·5 per cent had enlarged spleens.

Immunity from malaria is reported from the Godavari and Kishna deltas in Madras. The dispensary returns from these two districts show that during 1918 among a total of 449,614 and 363,107 out-patients admitted for treatment in these two districts only 5·5 and 3·1 per cent., respectively, suffered from malaria. In 1855, Baird Smith in his report on Irrigation in Southern India, remarked upon the freedom from malaria enjoyed by the delta tracts of the Cauvari and Colaroon Rivers, which have been irrigated for hundreds of years by flow irrigation. This is borne out by the dispensary returns for 1918, which show only 11,237 cases of malaria among 589,726 patients admitted for treatment, giving an astonishingly low fever index of only 1·9 per cent. The delta of the Mahanadi river in Orissa, although not quite so free of malaria as the Madras deltas just mentioned, also enjoys when compared with Bengal a relative immunity from the disease. The dispensary reports for 1919 show that malaria cases represented only 11 per cent. of the total admissions for treatment, which compares favourably with 25 per cent., the figure for Bengal as a whole, and 50 per cent., that of many of the more unhealthy areas.

Deltas may become intensely malarious.—Deltaic areas, though naturally healthy so long as they are not interfered with, are yet almost always potentially malarious. Besides the case of Ravenna, numerous instances may be quoted of deltas that have become notorious on account of the prevalence of malaria. For example, speaking of the Tuscan Maremma, a malarious tract watered by the Cecina Corma, Pecora, Bruna, Ombrone and Albegna rivers, Baird Smith remarks:

"It is to the disorganization of these rivers that the ruin of a tract, which nature has endowed with the richest of soils and the mildest of climates. . . with plains affording abundant pasture and fit for any kind of cultivation, is chiefly to be attributed."

India, too, can show examples of once prosperous delta areas sinking into a state of decay through agricultural decline and epidemic malaria and then being restored once again to a condition of health and prosperity by the reorganization of their river systems. The Tanjore and the Rajahmandry districts in Madras, which have both passed through these experiences within the last century, are striking instances. Much of Lower Bengal, on the other hand, is suffering at the present moment from disastrous changes similar to those which once threatened the existence of the more favoured deltas just mentioned. In this case the disorganization of the rivers has been largely brought about or at least greatly hastened by human interference.

Bengal a Country of Deltas.—An examination of Bengal and its river systems shows that a very large proportion of the province is deltaic. The total area of the province is now 84,092 square miles, or, deducting the States of Cooch Behar and Hill Tippera, 78,699 square miles. Of this area, more than 75 per cent. is delta. The joint deltas of the Ganges and Brahmaputra alone cover from 50,000 to 60,000 square miles, and there are many smaller streams which possess deltas of not inconsiderable size.

Owing to their extraordinary fertility, deltaic areas tend to become densely populated and are relatively healthy and very prosperous as long as they remain subject to normal inundations with the spill water from their rivers. But changes tend to occur from time to time in deltaic rivers, and such changes are apt to be followed by consequences serious alike to the health and prosperity of the areas affected. Changes in delta channels are often due to natural causes, but there is reason to believe that many of those that have occurred in the delta channels of Lower Bengal during the past sixty years are of human origin, and have followed the embankment of the country for the purpose of improved communications." In this connection, too, it is significant that reports have come to hand quite recently of the serious extension of malaria in the delta tracts of Cochin China, owing, it is suggested, to the more rapid spread of infection that has followed upon the improvement of communications. But the improvement of communications almost invariably means the construction of railways and roads; which in deltaic areas entails the multiplication of embankments; and these embankments, unless specially designed to avoid such results, eventually lead to the disorganzation of

the river systems; the dislocation of natural flush and drainage, and other disastrous consequences, as agricultural decline, depopulation and epidemic malaria, such as have occurred during the last sixty years in Lower Bengal.

In the deltaic portions of Bengal cultivable land, ordinarily subject to inundation with river water, never requires to lie fallow, whereas other lands do. Fallows, therefore, may be taken as an index of soil impoverishment. Embankments prevent inundation by river water.

In proportion to the cultivated area, fallow land is five times as common in both Western and Northern Bengal than in Eastern Bengal, and in Central Bengal the proportion of fallow land is just ten times as great as that in Eastern Bengal. In view of the facts stated, the multiplication of railways and roads in the deltaic portions of Bengal is to be regarded with grave misgivings. The embankments exert a most deleterious effect upon the fertility of the soil, thus causing a serious decline in the agricultural production of the areas they serve. Roads and railways afford, it is true, excellent facilities for the transport of goods and especially for the rapid transit of passengers. But these advantages may be too dearly purchased, if the construction of the necessary embankments brings about, as it may do, in course of time a 50 per cent. reduction in the agricultural outturn of whole districts, turning healthy areas into hot-beds of malaria and eventually leading perhaps to the destruction of nearly half their total population.

Recent observations have shown on numerous occasions that, following the construction of embankments, there is a very great local extension of malaria on both sides of the embankment, accompanied by a rise in the local mortality, an increase in the proportion of fever cases and fever deaths and a rise in the spleen index. Changes of this kind have been noted and specially reported on in detail in the case of the railway from Katwa to Sahibganj, in Birbhum and Murshidabad, in the case of embankments connected with the Sara-Bridge and in the case of the Sara-Sirajganj Railway. A considerable rise in the fever index has also been noted in the case of recent railway construction in Mymensingh.

The occurrence of outbreaks of malaria in association with the construction of embankments has never been disputed, and the observation in regard to the sudden increase of the spleen index in the neighbourhood of these embankments is conclusive. But the manner in which embankments bring about this admitted increase of malaria requires to be made clear, in order that adequate steps may be taken to remedy the condition and to prevent the further extension of the evil.

The Burdwan Fever Epidemic.—Enough has been stated to show that the embanking of the delta tracts of Bengal, whether for roads, for railways or for flood prevention, is almost invariably followed by the most disastrous consequences alike to health and to agriculture. This view is greatly strengthened by a consideration of the circumstances which led to the great Burdwan fever epidemic of sixty years ago. The special committee appointed in 1863 to investigate this epidemic fever, reported in 1864 that the area first affected by the disease had recently ceased to be inundated and enriched by flood water from the rivers.

A little earlier, Dr. Elliott, in a report on the "Epidemic Remittent and Intermittent Fever occurring in parts of Burdwan and Nadia Divisions," remarked that one of the principal causes of the epidemic was want of cultivation. He had almost invariably observed that the epidemic appeared first and was most virulent in the oldest and most populous villages, the lands in and around which had gone out of cultivation. Thus, while the fever committee showed that the fever was associated with relative infertility of the soil owing to lack of inundations, Dr. Elliott commented on the associated lack of cultivation. The one statement corroborates the other, for, as is well-known, lack of fertility leads to lack of cultivation.

The Effect of Embankments on Malaria.

How Embankments increase Malaria.—The increase of malaria that almost invariably follows the embanking of deltaic areas in Bengal is due to the interaction of a number of factors, most of which have a definite bearing upon the breeding of anopheles mosquitoes. The construction of embankments themselves leads, in the first place, to a great amount of excavation and the resulting borrow-pits afford additional breeding places for anopheles. But, except in rare instances, excavations of this kind are of relatively small importance, because enormous numbers of dobas and ditches and excavations of all kinds already exist in the immediate neighbourhood of all villages situated in deltaic areas. This is owing to the fact that every house has to be provided with a high earthen plinth raised well above the level of the inundation. In areas also where the houses are built of mud, as is the case in many parts of Central Bengal, building operations always result in extensive excavations. Hence villages in the delta tracts are all potentially malarious. But, ordinarily, however numerous and extensive the excavations of borrow-pits on a village site may be, they do not give rise to malaria so long as the greater part of the surface of the country is submerged by floods of river water during each wet season, for in these circumstances each hollow and depression is temporarily obliterated, so that anopheles mosquitoes cannot use them as breeding places. But should inundation cease or be prevented, every hollow which can hold rain water becomes a dangerous breeding place, and anopheles mosquitoes can thus multiply unchecked. Observations show that during the rainy season anopheles mosquitoes of various species, known to carry malaria, often occur in enormous numbers in the villages situated in embanked deltaic areas, whereas these insects are usually present in very scanty numbers at the same time of the year in areas that are actually inundated with river water.

ZIEMANN, H., M.D.—Remarks on Clayton-Lane's criticism of my monograph on malaria and blackwater fever in *Tropical Diseases Bulletin,* 1925, vol. 22, No. 4, p. 338, 89

GENERAL INDEX.

A

ABSTRACTS :—

Ankylostomiasis, carbon tetrachloride treatment, with note on hookworms of Penang, 139
Latrines and hookworm incidence on an estate, some notes, as diagnosed by Clayton-Lane centrifuge, 78
Malaria control measure, destroying engorged anopheles, 355
Small-pox and climate in India. Forecasting of epidemics, 307
Vibrios in human excrement, 97
Acid reaction, influence on virus of chicken sarcoma (Rous) and its importance in experiments of Dr. Gye, 159
Acquired immunity to malarial inoculation, further report, 48
Adhesions, cauterization in artificial pneumothorax treatment of pulmonary tuberculosis, 327
Africa, anatomical observations on yellow fever problem, 69
African schistosomes, "American" gongylonemas, zoo vermin and Italian cancer houses, refutation of statements made by Prof. R. T. Leiper, M.D., D.Sc., F.R.S., concerning, 314
Analysis of sprue stools, notes, 169

ANNOTATIONS :—

Albuminuria, production by renal vaso-constriction in animal and man, 111

ANNOTATIONS—*continued.*

Alopecia, congenital, 183
——, generalized, 307
——, persistent, production in rabbits by X-rays of various degrees of hardness, 91
Anæmia, blood-transfusion in pernicious, 304
——, sickle-cell, case in Sudan, 215
——, value of iron, 49
Ancylostome, ascaris, and trichuris infections, effect on health of West African native, 94
Ankylostomiasis among troops in Dehra Dun, 113
Antimeningococcus serums, comparison of potency polyvalency and therapeutic action, 381
Anti-rabic procedure in Palestine with special reference to decentralization of treatment, 94
Ascaridia perspicillum, studies of resistance of chicken to nematode, 110
Atherosclerosis and ingested cholesterol in rabbit, relation between, 325
Bacillus aertrycke (Mutton), relation between age and virulence of cultures, 401
——*dysenteriæ* Shiga as a vaccine, observations on employment of anaerobically-grown, 77
—— —— ——, report of typical and atypical, with special reference to agglutination reactions, 97
—— of paratyphoid group, 67
—— typhosus, variation in amount of soluble protein contained in old broth cultures, 114

ANNOTATIONS—*continued.*

Bacteria flagella, abnormal, in cultures, 212
Bacterial pollution and natural purification in Ohio and Illinois rivers, quantitative studies, 182
Bacteriological examination of water, correlation of sulphite reduction test with other tests, 15
Bacteriophage, studies on regeneration, 399
Beriberi in dog, gastric secretion in experimental, 166
Bilharziasis of female genital tract, 15
Bismuth compounds as revealed by Roentgen ray, intramuscular absorption of some insoluble, 161
Brazilian bubo, interesting case, 369
Bronchial affections, use of iodized oil in diagnosis and treatment, 214
Calcium absorption from intestinal tract in human subjects, 231
Carbohydrate, intestinal intolerance associated with overgrowth of gas bacillus, 165
Carcinoma, primary, of liver, 229
Chaulmoogra oil, fractionation, 14
Chilomastix gallinarum, morphology, division and cultivation, 339
Colitis, ætiology of chronic ulcerative, 112
Common cold, studies, 149
Constipations, non-surgical, functional and mechanical, 353
Creeping eruption, 113
Cultivation of *Herpetomonas muscarum* from *Lucilia sericata*, 412
Dengue, 162
Deodorization of coconut oil, 413
Depopulation of New Hebrides and other parts of Melanesia, 305
Diabetes mellitus, gastric secretion, 383
——, pathology, with special reference to pancreatic regeneration, 78
Differential fertility in United States, new data, 380
Dysentery carriers in Philippine Islands, contribution to question, 96
—— in India, important features in correct diagnosis, 163
Eczema, notes on ætiology, 167
Elephantiasis, syphilitic pesudo-, 37
Embadomonas cuniculi, morphology and cultivation, 382
Emetine periodide in treatment of *Schistosoma hæmatobium* infections amongst West African children, 412
Encephalitis in rabbits, geographical distribution of spontaneous, 307
——, medico-legal and sociological aspects of epidemic, 40
——, studies on ætiology of epidemic, 381
Epidemic disease in West Africa, 97
Erysipelas, 324
Erythema multiforme, 182
Erythrocytosis in artificially-inoculated malaria, 94
Fever resembling mild form of typhus fever, 183
Genus Strongyloides Grassi, biological studies on life cycle, 339
Giardia intestinalis, case treated with stovarsol, 400
Goitre, endemic, in New Zealand and its relation to soil-iodine, 110
——, exophthalmic, 214
—— ——, effect of compound solution of iodin and rest in surgery, 149
——, iodized salt in prevention, 214
——, salmon in diet for prophylaxis of, 199
Granuloma iguinale, ætiology with clinical report of three cases, 96
Guarnieri bodies, is formation an exclusively mammalian response to infection with vaccine virus? 380
Hæmic plasma cells, significance in various infective conditions, 40
Hæmochromatosis and chronic poisoning with copper, 183

ANNOTATIONS—*continued.*

Hæmolytic streptococci obtained from cases of scarlet fever, serological classification, 367
Hay's sulphur tests, clinical value for detecting bile acids in urine, 385
Herpetomonas elmassiani (Migone), relation to its plant and insect hosts, 66
Hexylresorcinol as internal urinary disinfectant, present status, 112
Hookworm and ascaris infections, treatment with carbon tetrachloride and oil of chenopodium, 95
—— diagnosis, place of smear, 402
—— disease in Mexico, observations, 401
—— ——, relation of type of soils of Alabama to distribution of, 164
—— ——, treatment of pregnant women with carbon tetrachloride, 166
—— infection, factors that influence rate of increase, 95
—— infections, light, evaluation of methods of Stoll and Lane and accuracy in diagnosis of Willis flotation method, 400
—— infestation and re-infestation in Ceylon, 164
—— ——, comparison of Stoll and Lane egg-count methods for estimation, 378
—— —— in Alabama, intensity, 95
—— larvæ, observations on development, 384
—— re-infection, 95
—— reinfestation for three years after treatment in sanitated area in Porto Rico and its bearing on permanent hookworm control in group studied, 401
——, studies and observations on soil infestation in Southern Alabama from October, 1923, to September, 1924, 164
Hookworms, estimation of number harboured, by use of dilution egg-count method, 385
——, rate of loss in absence of re-infections, 143
Hydatid disease, mechanism of daughter cyst formation, 324
Hypertension, action of hepatic extract, 402
Immunity, rôle of reticulo-endothelial system, 325
Infectious disease of skin, use of mercurochrome-220 soluble in treatment of, 165
Kala-azar, epidemiological consideration of transmission, 381
—— in India, epidemiological consideration of transmission, 398
——, study of incidence in certain parts of North Behar, 325, 401
Laboratory evaluation and classification, proposed method, 402
Lagocheilascaris minor, case of infection, 380
Larval trematode infestation of fresh-water mollusc of San Juan Island, Puget Sound, 12
Leishmaniasis, cutaneous, further observations on transmission to man from *Phlebotomus papatasii*, 383
—— —— reaction, 149
Leper's sera, serological analysis, 179
Leprosy, formol-gel reaction, 14
——, new method of diagnosis and vaccine treatment, 216
——, studies on serology, I, 354; II, 353
——, treatment by vaccine of autolysed tubercle bacilli, 216
—— —— with compounds of antimony, 14
—— —— —— derivatives of chaulmoogra oil, 10
——, Wassermann reaction, Kolmer's new complement-fixation test, and Kahn precipitation test, 14
Leukoplakia buccalis, 67
Lobar pneumonia, nasal passages, 181
Lung tumours, primary, in mice following cutaneous application of coal tar, 78
Lymphatic leucæmia, neoplastic nature and its relation to lymphosarcoma, 381
Madura foot (mycetoma), 112

ANNOTATIONS—*continued.*

Malaria in Palestine, epidemiology, 351
—— —— Trinidad, B.W.I., some observations on malignant tertian, 77
——, mountain, field study in Brazil, 97
Malarial fevers in U.S. Army and at selected stations, 306
—— fever, treatment, 49
Malignant disease, remarks on new flocculation reaction for serodiagnosis, 66
Medical aspects of life insurance in India with special reference to Calcutta, 412
Medical research in China, 163
Melioidosis: disease of rodents communicable to man, 13
Meningitis due to *Bacillus enteritidis* Gaertner, 385
Mercuric chloride poisoning, acute, 144
Micro-organisms, group, transmitted hereditarily in ticks and apparently unassociated with disease, 50
Miliary lichen planus, 96
Military service in Tropics, and its effect on health and efficiency, 306
Milkweed flagellate, *Herpetomonas elmassiani* (Migone), geographical distribution, 64
—— —— in Maryland, non-pathogenicity, 93
Modifying course of infections with bird malaria by changing sugar content of blood, 380
Moniliasis, case of pulmonary, 12
Myocarditis, syphilitic, in rabbit, 231
Mycosis fungoides. Its relation to leukemia and lymphosarcoma, 93
Neoplasms, causation of malignant, 338
Nephritis, relation of albuminuria to protein requirement, 132
Neurosyphilis, treatment by malaria, 182
—— —— with tryparsamide, 162
Observations on pathology of central nervous system in malignant tertian malaria, with remarks on certain clinical phenomena, 343
Occupational disease among zinc workers, 382
Œdema, angioneurotic, 214
Ohara's disease and tularæmia, identity, 212
Onchocerca volvulus, development in *Simulium damnosum*, 111
—— —— Leuckart, contribution to study, with some observations on its prevalence in Nigeria, 167, 216
—— —— ——, further development in *Simulium damnosum*, Theob., 401
Oral infection with ankylostoma, studies, 382
Oriental sore, emetine hydrochloride in treatment of, 76
Oroya fever, ætiology, 354
Osteomalacia in China, 40
Paralysis, occurrence after treatment with antirabic vaccine, 132
Paramecia of blood-serums, effect, especially from patients with carcinoma, 113
Paratyphoid-enteritidis infection of white mice, microbic virulence and host susceptibility, 111
Pemphigus, unusual type, 351
Peritonitis, pneumococcic and streptococcic, 132
Plague and regulation of numbers in wild animals, 66
Plankton, relationship to Anopheline larvæ, 381
Plant-food constituents of Philippine guano, nature and availability, 354
Pneumococcus growth inhibition, studies, 325
Pneumonia, epidemiology, 399
Poliomyelitis, epidemic bulbar. Report of six cases with one necropsy, 108
Principles in the testing of a cure, 412
Proteins, urinary, 215
Protozoa, stool examination, 94
Queensland, tropical, observations on white working population, 181
Quinine, experiments on administration in watery solution in olive oil, 229

ANNOTATIONS—*continued.*

Quinine, hæmoglobinuria in man, certain observations on mechanism, 144
——, rectal injections, 163
Rabies fixed-virus, rate of multiplication in rabbits, 144
Rat-bite fever, experimental studies with spiral organism found in wild rat and identical with organism causing, 50
—— fleas, destruction by heat on board ship, 148
—— poisoning, outbreak, probably due to rat virus, 149
Recklinghausen's disease without tumour formation, 112
Ringworm of scalp in adult, 179
—— species in toes, morphologic variations, 139
Rocky Mountain spotted fever, 13
—— —— —— —— tick, *Dermacentor andersoni*, cultivation of rickettsia-like micro-organisms, 231
Rheumatic fever, acute, study of hemolytic streptococci with analysis of antigenic relationship existing among certain strains, 94
Scarlet fever, 181
—— ——, studies on epidemiology, 383
Sickle-cell anæmia in Sudan, case of, 166
Sleeping sickness, second case in Sudan caused by *Trypanosoma rhodesiense*, 385
Sodium citrate injections, changes in respiration, circulation and coagulation time of blood produced by, 161
Spirochætosis bronchialis, case of, 13
Spontaneous disease, effects on organ weights of rabbits, 113
Sporotrichosis in man, 112
Street risk of carbon-monoxide poisoning, 410
Studies on the serology of leprosy. III: The Kahn precipitation reaction in leprosy, 413
Syphilis and other skin diseases, blood cholesterol finding, 166
——, bismuth in treatment of, 96
——, curative effect of bismuth compounds in experimental rabbit, 93
——, intravenous administration of sulpharsphenamin, 147
——, resistant, protein as adjunct in treatment, 130
——, tryparsamide, 15
Syphilitic alopecia: its relation to neuro-syphilis, 158
Trachoma in Philippine Islands, preliminary report on control, 108
Trichomonas buccalis, studies, 166
——, cultivation, thermal death-point anaerobic conditions, attempts at sterilization, 383
Trophozoites of intestinal protozoa and their bearing on function of cysts, animal infections, 380
Trypanosome infections, susceptibility and resistance, 324
Trypanosomes, mode of action of Bayer "205," 215
Tuberculosis, effect of parathyroid on certain signs and symptoms in, 353
—— in the Tropics, 39
——, pulmonary, incidence in Colombo as indicated by examination of sputa found in public places, 95
Typhoid fever in Cochin China, 167
Ulcer, gastric and duodenal, 181
Ulcers, healing of gastric, 114
Uncinariasis, employment of carbon tetrachloride followed immediately by magnesium sulphate in treatment of, 93
Urinary tract, hexylresorcinol in infection of, 166
Urobilin physiology and pathology, studies, 306
Varicose ulcers, new application, 165
Viable bacilli, proportion in agar cultures of *Bacillus aertrycke* (Mutton), with special reference to change in size of organisms during growth, and to capacity to which they give rise, 386
Wild rats, disease with gross pathology resembling plague, 76

Artificially induced malaria, Whittingham (W) strain, 117
Artificial pneumothorax treatment of pulmonary tuberculosis, cauterization of adhesions, 327
Aspects, some, of malaria control, 185
Association of different species of organisms in production of certain biochemical phenomena and in causation of certain diseases and certain symptoms of disease, observations on importance of symbiosis or close, 217

B

Bacteria, plants and vertebrates, virus diseases, 17
Bengal, epidemic of cholera amongst ballast train coolies, 196
Bilharzia parasite in South Africa, environmental influences which favour development and spread. Food supply of "Physopsis," 89
Biochemical reactions, brief note, of certain fungi, viz., *Monilia krusei*, *M. macedoniensis*, and *M. tropicalis*, 47
—— —— of *Vibriothrix zeylanica* Castellani, brief note on morphology, cultural characters and, 371
Blatta orientalis in England, preliminary note on study of *Endamœba blattæ* (Butschli, 1878) Leidy, 1879, found parasitic in intestine of, with some remarks on its generic status, 41
Brill's disease, tropical typhus and, 374
Bronchomycosis, notes on case, 145

C

Cancer field commission in Trentino, 1925, entomological notes, 294
——, observations and researches on epidemiology, made in Holland and Italy (May-September, 1925), 233
Cancerous and other tumours in animals collected by Dr. Sambon during his recent researches, examination, 298
Carbon compounds, further observations on mycological method to identify various sugars and, 201
—— tetrachloride, chenopodium and thymol in treatment of hookworm infection, ankylostomiasis: comparative efficiency of, 101
Cattle, further experiments with *Gongylonema*, 194, 346
Central nervous system in malignant tertian malaria, observations on pathology, with remarks on certain clinical phenomena, 343
Chenopodium-carbon tetrachloride, hookworm control with, 227
Cholera, epidemic amongst ballast train coolies in Bengal, 196
——, prevention and treatment by essential oils, 210
Clayton-Lane's criticism of my monograph on malaria and blackwater fever in *Tropical Diseases Bulletin*, 1925, vol. 22, No. 4, p. 338, remarks, 89
Climatic bubo, or subacute inguinal poradenitis, 103
Comparative efficiency of carbon tetrachloride, chenopodium and thymol in treatment of hookworm infection, ankylostomiasis, 101
Control of malaria mosquitoes, airplane dusting, 311
Coolies in Bengal, epidemic of cholera amongst ballast train, 196
Corneal ulcer in malaria, note, 3

CORRESPONDENCE :—
Lane, Clayton-, 200

Cultural characters and biochemical reactions of *Vibriothrix zeylanica* Castellani, brief note on morphology, 371
—— investigation, and morphological, of *Vibriothrix zeylanica* Castellani, 44

CURRENT LITERATURE :—

Original Communications.

FURTHER RESEARCHES ON THE PRESERVATION OF INSULIN.

By Prof. E. Trocello
AND
Dr. A. Cruto.

In a communication to the XXXth Italian Congress of Internal Medicine [1] we minutely described some of our experiments on the resistance of insulin at high temperature. We were induced to carry out these experiments by some communications published by English authors, who, having used insulin of a different origin, had noticed that it lost its medical power in tropical climates, so that after a few months the deterioration practically rendered the drug useless.

The conclusions of our experiments carried out with Italian insulin, were as follows:

The insulin, kept constantly at high temperature, even for a long time, maintains its hypoglycæmic property integrally, or remarkably well.

The preparation kept in solid form shows itself incontestably more resistant than insulin in liquid solution. In fact, in the experiments at 100°, for twenty-four hours, and in the experiments at 42° for thirty-five days, the property of the former was in no way modified, while the latter lost about one-half of its hypoglycæmic property and did not cause convulsions. Another consideration on the resistance of the experimented insulin, is the length of its duration at a high temperature. The solid preparation, in this respect, in the limited time of the experiments (twenty-four hours at 100° and fifteen and thirty days at 42°) did not undergo any alterations at all. Insulin in solution form appeared to be peculiarly influenced by the time of the exposure; in fact, while it resisted integrally the temperature of 100° for ten hours, it lost about one-half of its hypoglycæmic power, both at the temperature of 100° in twenty-four hours and at a temperature of 36° in sixteen and thirty-four days. In consequence, we get the following practical corollary in relation to the preservation in tropical climates of insulin experimented with by us: The possibility of preserving the original hypoglycæmic properties even at very high temperature and for a considerable length of time.

These experiments were carried out with "Insulin Ergon" prepared in the Instituto Nazionale Medico Farmacologico of Rome.

Nevertheless, the important problem of the preservation of insulin in tropical climates could not remain unsolved, and last year new experimental laboratory investigations were carried out, especially by English authors in India.

These investigations appeared particularly necessary as some clinical results seemed to strengthen the idea of quick deterioration. In fact, Stott [2], in India, had met with a progressive loss of activity in twelve diabetics when the drug was kept at room temperature. When the medicament arrived in India it possessed a glucosic equivalent of 12 gr. per unit and gradually went down to 1 gr. or less, in six months.

It is true that other authors come to different conclusions. For instance, Bose [3] has been able to observe in India, that at a temperature of 35° for one month, insulin did not undergo any deterioration at all.

In a more recent paper, in *The Lancet*, Neave Kingsbury [4] exposed a succession of experiments carried out with American insulin on rabbits of different origin. He concluded that a sample of insulin kept at tropical temperature for six months, and injected into local rabbits, seemed to immediately undergo a deterioration of about 40 per cent. On reckoning the results obtained on rabbits of first generation and originating from animals recently imported into the tropics, showed but little or no deterioration.

Moreover, the author draws some conclusions on the factors which would have an influence on the preservation of the drug, and attributes them to the purity of the preparation and the acidity of the insulin solution; this, besides the mentioned importance on the variety of the animals used for controls.

Our new researches were carried out on samples which had previously appertained to the preparation used last year for the first experiments.

A.—Insulin kept in Incubator at 42° for three months.

Experiment No. I.

Solid Insulin.

(January 7, 1925.) Rabbit ♂, weight 1,730 grm.
Time, 9.25, injection of 2 mg. of insulin
,, 11.10, typical convulsions
,, 11.15, glycæmia = 0·44 per thousand

Experiment No. II.

Insulin in Solution.

(January 7, 1925.) Rabbit ♂, weight 1,400 grm.
Time, 9.30, injection of 0·3 c.c. (10 units per c.c.)
,, 11.30, glycæmia = 0·81 per thousand
No convulsions.

B.—Insulin kept in Incubator at 37° to 40° for one year and twenty days.

Experiment No. I.

Solid Insulin.

(October 28, 1925.) Rabbit ♀, weight 1,510 grm.
Time, 9.15, injection of 2 mg. of insulin
,, 11.25, glycæmia = 0·50 per thousand
,, 13.45, typical convulsions

Experiment No. II.

(October 29, 1925.) Rabbit ♂, weight 1,800 grm.
Time, 11.55, injection of 2 mg. of insulin
,, 14.15, glycæmia = 0·47 per thousand
,, 14.20, typical convulsions

Experiment No. III.

(October 29, 1925.) Rabbit ♂, weight 1,430 grm.
Time, 12, injection of 2 mg. of insulin
,, 14.20, glycæmia = 0·53
,, 15.30, typical convulsions
,, 15.35, glycæmia = 0·42

Therefore, we may conclude that:

The insulin experimented with by us and kept in solid form in incubator at 37° to 40° for more than a year, retains the hypoglycæmic property which it had soon after its preparation, and its power of causing convulsions.

At high temperature, if suitably prepared and preserved in solid form, insulin remains unaltered.

On the other hand, kept in liquid solution, the insulin shows a loss of about one-half of its power already after thirty-three days (42° to 45°), and after three months (42°) a nearly complete abolishment of the hypoglycæmic properties and a total disappearance of the convulsive ones.

Relating to the results of Cheadle [5] on the influence of the acidity of the insulin solution, some other considerations can be made. Cheadle has proved that in autoclave at 125° for twenty minutes, the solution with pH=2 would lose 20 or 25 per cent. of its power, while that with pH=4 would lose it completely. And such phenomena would appear to relate to a disassociation by the product, if kept in solution.

The preservation of the solid form, if the hypothesis be true, appears to be the most indicated.

In any case, the fact is that neither high temperature nor time has any influence on the biological properties of the drug kept in solid form. Further, that the age and origin of the animals used for insulin properties have rather a great importance and give reason for the different results obtained by various authors, cannot be rejected by anyone.

Also in our temperate climates some differences, not very important ones, can be observed between rabbits of different breeds. From this arises the corollary that only animals recently imported from temperate climates should be experimented with in the tropics.

As regards the other consideration of Neave Kingsbury, on the purity of the product, which would give reason to the fact that, in tropical climates, some preparations keep better than others, it can be observed that there is not anything more likely. The fact of maintaining itself better in solid form than in liquid solution strengthens the hypothesis and proves the easy susceptibility of the product to impurity of all kinds.

SUMMARY.

Insulin should be kept in solid form because, as shown by experiments, it does not undergo any alteration at a high temperature, and can be preserved for an unlimited length of time. The cause of the difference in preservation of insulin in liquid form lies in the fact that a hydrolysis of the product causes a deterioration in its pharmaco-dynamic properties.

THE PROTECTION OF THE HEAD AGAINST THE SUN'S RAYS IN TROPICAL AFRICA.

By J. F. CORSON.

IT is very generally believed by European residents in tropical Africa that exposure of the head to the sun's rays for even a brief period, unless protected by an opaque covering, is likely to cause not merely discomfort but serious results. A chink in the grass roof of a hut, or the admission of a few rays of light through the ventilation aperture of a "Wolseley" helmet is regarded with misgiving. The supposed harmful influence is often attributed to penetrative power of light rays or ultra-violet rays rather than to heat. Manson suggested that some peculiar physical action of the sun's rays on the tissues might be the cause of that class of cases called sun-traumatism. It appears to be established, from numerous observations, that the sun's rays of short wave-lengths have very little penetrative power, hardly, if at all, beyond the skin. There is no reason to suppose that the scalp may be different from other parts of the skin in regard to the possible formation of chemical substances by the action of rays. It appears also to have been shown conclusively that heat-stroke is due to overheating of the body associated with failure of the natural heat regulation. Local heating of the central nervous system to a harmful degree is theoretically possible, but is unlikely to occur without a corresponding greatly increased temperature of the skin and subcutaneous tissues. Temperatures of 109·4° F. to 111° F. have been observed within helmets without apparently causing discomfort to the wearers (Wanhill, quoted by L. Hill). There is no doubt that a light, white helmet fulfils the requirements of great reflection and little penetration and provides a moderate degree of ventilation. A helmet, however, at its best is a heavy and clumsy form of hat and is discarded with relief when it is thought safe to do so. A few somewhat rough experiments were made in Dar-es-Salaam during the months of August, September and October, 1925, to see whether some lighter head covering might safely be used. A Panama hat was selected as a possible suitable substitute. Some tests were made to compare the heat-excluding qualities of some forms of hat, viz., a man's white "polo" helmet, a lady's white pith helmet, a Panama, a man's soft dark-grey felt hat, a lady's light-grey tropical hat of thick felt and a red fez with loose black calico lining. The conditions were not severe as regards heat rays as the maximum shade temperature during the period was only 86° F. to 88° F. and a fairly strong breeze was usually present. Exposures to the sun for various periods and at different heights from the ground were made, clinical and other thermometers being used to record the maximum temperatures inside the hats. The results were in accord with similar experiments by various observers. The felt hats and the fez showed high temperatures, 105° F. to 112° F., with exposures of from ten minutes to half an hour and longer, whilst the thermometers inside the helmets never

rose above the original setting of 97° F. or 98° F., and the Panama rarely showed a temperature above 100° F. under similar conditions. The lady's felt hat, a heavy article said to be intended for use in the tropics, showed an inside temperature of 108° F. after exposure for two hours. Using the man's felt hat to represent the scalp, the temperature of its upper surface, when covered by the Panama, rose to 100° F. with one hour's exposure and on another occasion to 102·2° F. with four hours' exposure at the hottest part of the day. Some personal experiments were also made. With the bulb of the thermometer in contact with the parietal region of the scalp, five minutes' exposure, when wearing the felt hat, raised the temperature to 102·4° F., whilst when the Panama was worn, an exposure of forty minutes, from 11.50 a.m. to 12.30 p.m. caused a rise to 99° F. only. On the afternoon of the same day, the Panama being worn with continuous exposure from 2.30 p.m. to 4 p.m., the temperature of the scalp, tested from time to time, was only 99° F. On one occasion the bare head was exposed to the sun from 2 p.m. to 2.30 p.m. The temperature of the scalp or hair, taken by stroking with the bulb of a clinical thermometer, rose to 104° F. within six minutes, and to 105·1° F. in twenty minutes, and did not rise higher. The temperature of the body, taken in the mouth, did not rise above normal within an hour. Except for the tingling feeling of radiant heat during the half hour, which was most felt in the first few minutes, no discomfort was experienced either at the time or later. The dry bulb temperature at the time was 82·7° F., the wet bulb 77·3° F., and the maximum temperature of the day 88·8° F. There was a moderate breeze. Throughout the period from August to October the Panama hat was used instead of a helmet. On several occasions there was continuous exposure to the sun throughout the afternoon from 2.30 p.m., though the conditions of daily work usually involved very brief periods of exposure. No unpleasant symptoms were experienced.

Conclusions.

(1) Under the mild conditions that prevail for considerable periods of the year in many parts of tropical Africa, a light form of hat with good reflecting power, such as a Panama, may safely be used instead of a helmet, at least when the circumstances of daily life do not require prolonged exposure to the sun.

(2) While such states of bodily health and such external conditions as are known to conduce to over-heating of the body with diminished heat loss, should be guarded against, there is a tendency to attach an exaggerated value to the penetrative power of the sun's rays in tropical Africa.

A NOTE ON CORNEAL ULCER IN MALARIA.

By R. E. McConnell, B.A., M.D.,

and

C. M. McGill, D.T.M.Liv.

Barranca-Bermeja, Colombia, South America.

Statistics on the subject of corneal ulcer as a complication of malaria are not available here, but it must be relatively uncommon as in a contact with some thousands of cases in various parts of the world I had not met with any until the case under present consideration. The only intrinsic interest in this case is that the patient developed malarial symptoms only twice in his life, and on both occasions this complication presented itself. The description of the first attack is from the hospital records augmented by recollections of those in attendance.

R.W., a robust Canadian of 46 years, was admitted to hospital April 28, 1924, with a high temperature and typical symptoms of malaria. A thin blood-smear was negative, but the clinical symptoms pointed to the infection being that of malignant tertian. On the third day, when the temperature had fallen to normal, what was originally diagnosed as severe conjunctivitis appeared in the right eye. For several days there was considerable pain in the eyeball. A transparent, faintly grey ulcer was then found below the pupil, which later became lead-coloured for a time. It grew larger by budding. Boric acid washes were first used, then procaine and argyrol for some days and then again boric acid, with the silver compound every third day. The eye was padded. By May 16 the conjunctival injection had cleared up. On July 10 he was sent to New York on account of the anxiety

caused by the persistent macula, but by the time he arrived there he was pronounced by a specialist fit to return at once. The macula subsequently cleared up completely.

On September 3, 1925, he was admitted again under the immediate care of Dr. R. H. Eisaman, and showed malignant tertian parasites. He was discharged on the 9th. On the 11th the right eye began to trouble him while on night duty and in the morning he noticed that vision was dimmed. The eye became very red and painful and by next day was at its worst. There were pain and photophobia. He came into the hospital on the 19th, when an irregularly round almost transparent ulcer a quarter-inch in diameter was found, paracentral, a little below and to the inner side of the pupil. Both palpebral conjunctivæ were very red, while the circumcorneal injection was faint and confined to a narrow band. The ulcer was touched twice with ionine, atropine instilled twice, a shade applied and on the 24th he was discharged with no sign left other than a slight unevenness of the surface where the ulcerous area had been.

I think it is safe to assume that both of these eye attacks were herpetic. No other herpetic eruption manifested itself. It seems probable that in these cases a guiding treatment is preferable to one of energetic medication and interference.

BILHARZIA TREATMENT. EXPERIENCE GAINED FROM MORE THAN 3,000 TARTAR EMETIC INJECTIONS. PRECAUTIONARY MEASURES. RESULTS OBTAINED.[1]

By Dr. P. H. J. Lampe,

Surgeon to the Dutch East-Indian Army, Paramaribo.

For many years it has been customary in the Military Hospital of Paramaribo to treat certain tropical diseases such as venerial granuloma, leishmaniasis, bilharziasis, filariasis and some cases of ulcera cruris, with intravenous injections of tartar emetic.

The results obtained were—with the exception of some cases of venerial granuloma and leishmaniasis—only relatively satisfactory. The curative value of this remedy was therefore accepted by the medical men of this Institute with reserve. Moreover, often undesirable, sometimes dangerous complications were observed.

My personal experience during 1923 and 1924 (which included many cases of leishmaniasis, filariasis, bilharziasis and ulcera cruris) made me doubt the specificity of this remedy.

Reading the literature, however, made it at once become plain to me that unfavourable results—especially in bilharziasis, so flagrantly in contrast with the results obtained in Egypt, South Africa, China and Japan—were undoubtedly due to the too small doses given in this country.

Of late years a copious literature bearing on bilharzia treatment has accumulated. Those interested I may refer to the list at the conclusion of this communication.

Briefly the conclusion arrived at is that tartar emetic—provided necessary precautions are observed and a sufficient dose is given—will cure every bilharzia patient of his parasitism, without appreciable harm, with the exception of a few cases showing intolerance.

According to Christopherson, the recognized authority, a dose of 25 to 30 gr., i.e., + 1·620 to 1·950 grm. of tartar emetic within twenty-five to thirty days intravenously injected is sufficient (*Lancet*, September 7, 1918; *Journal of Trop. Med. & Hyg.*, July 1, 1920; my own correspondence, 1925).

It might be expected that the application of these large quantities of tartar emetic in a relatively short period would emphasize the complications so often observed.

Since it was thought possible that these ill results were due to impurities, the miltary apothecary Vonk analysed the whole quantity of tartar emetic in stock for possible impurities.

The report of this analysis, of considerable value to successful tartar emetic therapy, follows:—

"In connection with a communication of Meleney ('Schistomiasis japonica,' *United States Naval Med. Bull.* 881, No. 5) that Christiansen and Norten ('Some Observations on Tartar Emetic,' *Journ. Lab. and Chin. Med.*, 1923, ix, 35) are drawing attention to the fact that most of the tartar emetic appearing on the market for medical use contains lead, arsenic and iron as impurities, beside the insoluble and poisonous antimonium-oxide, the consignments of tartar emetic then present in the store of the Military Hospital were examined for these impurities.

"The consignments were received in 1905, 1911, 1916, 1924 and 1925.

"All were obtained from the Government magazine of chemicals at Amsterdam.

"It appeared that only the consignment of 1916 was pure. Besides a trace of chloride, that of 1915 contained a trace of chloride and also a trace of heavy metal; and that of 1911 had, moreover, a trace of sulphate. The solution of the consignment of 1924 was turbid and yellowish, and contained heavy metal as well as potassium hydrotartrate.

"The solution of the consignment of 1925 was dark yellow, contained plentiful sulphate, some potassium hydrotartrate and also a trace of chloride and heavy metal.

"The older consignments were in fact of a better quality. By repeated recrystallization, aided by strong suction, a preparation was got that answered the analytical (value determination) as well as the following tests, to which, in my opinion, *tartras kalio-stibicus pro injectio* should be put.

"These tests are obtained partly from the Dutch

[1] Communication from the Military Hospital of Paramaribo, by Chief P. Cool, Surgeon-superintendent to the Dutch East-Indian Army.

Pharmacopœia and partly from E. Schmidt's 'Pharmaceutische Chemie.'

"The 5 per cent. solution should be perfectly clear and colourless; neither barium nitrate, silver nitrate, nor ammonium oxalate should cause in this solution a precipitate or an opalescence within five minutes.

"When to a solution in concentrated hydrochloride acid, 1 gr. to 4 c.c., an equal volume of stannochloride is added, the liquid should not become turbid or discoloured.

"The 5 per cent. solution should, if mixed with an equal volume of 1/10 N thiosulphate, remain clear for at least five minutes at a temperature of 25° C. When to 5 c.c. of the 5 per cent. solution be added so much pure nitrium hydroxide solution, so as entirely to redissolve the precipitate at first appearing, the addition of concentrated hydrosulphide solution should cause neither precipitate nor discoloration.

"The present Dutch Pharmacopœia does not mention tests in relation to clearness and colourlessness of the solution, does not demand the absence of calcium and heavy metals, and prescribes a reaction on chloride and sulphate in a solution of 1 per cent. (see Schoorl, Ph.W., '07, 1020 and 0'4, 866).

"The perfectly pure tartras kalio-stibicus is nowadays dissolved, 1 to 100, in a solution of 0'7 per cent. NaCl *purissimum*, filtered through wet, hardened filter-paper and, as shortly as possible before the injection, sterilized for a full hour in a vapour current of 100° C.

"The solution is then contained in nearly fully filled vials with ground-stoppers, tied up with paraffin paper."

For bilharzia treatment the tartar emetic purified in the above manner has been used since January, 1925, and the 1 per cent. solution in physiological solution is prepared and sterilized the night before each injection day as late as possible.[1]

During the treatment the urine is regularly tested for albumin and casts. The patients have always to report all symptoms experienced after the injection (coughing, vomiting, pain in the muscles or joints, fever, ague, headache, short-windedness, palpitations, itch, eczema (eruption), œdema, &c.), and also diseases (malaria, filaria, bronchitis, angina, &c.). Symptoms however mild should be noted.

Every item is noted on the patient's case sheet, so that the dose injected may be reduced or the injection suspended. The patient remains seated under observation for a quarter or half an hour. After this rest the patient can take the often long homeward journey without inconvenience. The most seriously infected area is at about two hours' walk from the Military Hospital.

The routine treatment of bilharzia patients is:—

Thrice a week, after three injections of 3 c.c., 5 c.c. and 7'5 c.c. respectively, 8 to 10 c.c. of 1 per cent. tartar emetic solution is injected up to a total of 150 to 200 c.c.

Treatment takes about six to seven weeks. Adults in less favourable health condition (chronic malaria, anæmia, touch of cachexia, &c.) receive proportionally less. Children aged 12 years receive 100 to 125 c.c., 5 to 6 c.c. each injection; children of 8 years, 80 c.c., 3 to 4 c.c. each injection.

The clinical treatment of in-patients—excepting serious cases of lung and hepatic disorders—is somewhat altered.

These patients, under regular control and not working, get 8 to 10 c.c. six times weekly, after three preceding injections of 3'5 and 7'5 c.c., and are injected with a total quantity of 200 to 240 c.c.

Treatment in such cases lasts from four to five weeks. This undoubtedly "very strong tartar emetic treatment"—50 to 60 c.c. of the purified solution injected weekly—was, without exception, easily borne by all the patients (fourteen adult males, negroes and creoles). To Javanese and Hindoos this intensified treatment was, as a rule, not applied.

Regular notes was kept of all possible disturbances occurring during and after the treatment:—

(i) *Rheumatic pains.*—Many adult patients (75 per cent.) suffered from slight rheumatic pains in the muscles and the main joints; about 30 per cent. complained of their own accord. All of them, however, could uninterruptedly continue their occupations in the field, although a few may have ceased coming for treatment on that account.

These pains mostly appear the day after the final injection and may last to the next day. It is most interesting that I never heard any such complaint from children, not even after having asked (sixteen patients of less than 14 years), who receive relatively more tartar emetic than the adults.

(ii) *Tussicular irritation.*—This was fairly regularly observed in the case of four patients (amongst whom were two children), immediately after each injection. A slight reduction of the dose, and eventually a small dose of codeine, helped excellently.

(iii) *Inclination to vomit.*—In the case of a patient (adult male) this occurred so regularly that the dose per injection had to be reduced to 5 c.c. and the total dose to 100 c.c. Notwithstanding that, this patient, whom I had been able to control regularly since discharge from the hospital, is permanently cured. The parasites have apparently suffered more than the patient (? retarded excretion, ? higher concentration in the blood). The inclination to vomit now and then was easily overcome in the case of six adults. One patient vomited after the first injection (3 c.c.) and was not further kept under treatment.

(iv) *Salivary flux.*—Once observed.

(v) *Headache* (without albuminuria).—Two females complained of this during the treatment. One female still complains of headache (four months after discharge) and blames the treatment for that (albumin −, *Ankylostoma* +).

(vi) *Œdema* (without albuminuria).—Thrice a localized œdema was observed, twice on the volar

[1] The use of tartar emetic from a vial that has been opened has to be warned against. It appears that, even in observing the ordinary aseptic precautionary measures, infection may be brought about by fungi, for which this solution is an excellent nutrient.

part of the hand and wrist (one-sided), once on lips and chin. It was a passing and painless swelling, lasting only a few days.

(vii) *Albuminuria*, not observed before, was observed in the case of a female patient after the

FIG. 1.—Clinical case of native with *Schistosoma mansoni*. Wasting of face and body. Much ascites due to cirrhosis of liver and miliary bilharzial peritonitis. Œdema of lower extremities.

administration of a total dose of 120 c.c. She had no other complications. Esbach varied from ½ to 1 per cent., and hyaline cylinders were found in the sediment.

(viii) *Itching, urticaria, pustulous eczema.*—Especially on the extensor side of the extremities, sometimes over the entire body. Itching was repeatedly met with; urticaria as well; in the case of three adults an at first persistent eczema appeared, slowly improving during the continued treatment. These symptoms appeared "only after the final injections."

(ix) *Fever, ague.*—It is not possible to decide whether fever and ague, often observed, are always due to malaria, filaria, &c., or whether they are due to the tartar emetic.

(x) *Icterus.*—A slight icterus, lasting five weeks, occurred in a patient three weeks after the treatment (220 c.c.). The patient suffered at the same time from fever and his blood harboured malaria plasmodia.

(xi) *Short-windedness, cardiac pains, palpitation.*—Observed in slight degree in one male and one female.

(xii) *Collapse.*—Only three times experienced in the case of anæmic patients, who had come a long distance; after the injection a faint of short duration and of not disquieting nature. Serious collapse never occurred.

In summing up it will be found that very often slight rheumatic pains appear, which are, however, so insignificant that even sensitive and easily complaining Hindoos can regularly carry on with their work during the treatment. Very seldom does it become necessary to stop the treatment on that account, injections being looked upon as quite an ordinary affair and have become even popular.

With children no undesirable complications, except the cough, immediately after the injection, have been noticed.

My expectation that certain agricultural centres in Surinam would prove seriously infested, is unfortunately true.

The fæces of 434 settlers of Kwatta chosen at random (district in the immediate neighbourhood of the city) were sent for examination. The conscientious control by the landowner guaranteed reliability.

Ninety-one of the 242 male Hindoo peasants were infected, 9 of the 37 female, 5 of the 153 children.

Of 68 people of Meerzorg collected at random, all peasants, 32 were infected. A small number of women and children investigated were not infected.

Later on I hope to examine further this district lying opposite Paramaribo city on the right bank of the Surinam river.

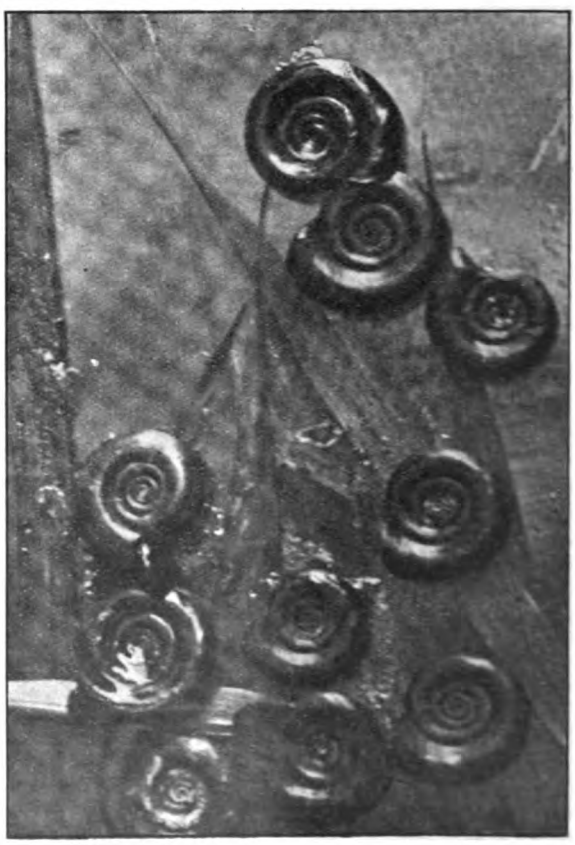

FIG. 2.—Photograph of shells of *Planorbis olivaceus*, the immediate host of *Schistosoma mansoni* in Dutch Guiana.

Thirty-one of 62 inhabitants of Charlesburg, an outlying quarter of Paramaribo, who for the greater part sent their fæces spontaneously for examination, were infected, viz., 21 out of 32 males, 3 out of 3 females, 7 out of 27 children.

In addition to these, 158 cases of bilharziasis came under my observation from January 1 to July 31; total in seven months, 326 cases.

My opinion is that practically all field labourers are infected in the endemic areas.

Simple examination of fæces can only partly disclose the number of infected. It often happens, after repeated, negative results, that bilharzia eggs are found at last. The examination of the fæces of labourers, regularly working under the same conditions on the same land where infested snails (14 per cent.) are met with, proved again and again that such examination gives positive results only for a percentage.

I have found living parasites in the portal vein, in cases which always presented negative results when their fæces were examined whilst in hospital. The same applied to patients in whom during a laparotomy typical bilharzial miliary peritonitis was encountered, without eggs having been found in the fæces.

Synopsis of Cases.

Of the 326 bilharzia patients, gathered from January to July, are:—

(*a*) 108 discharged, cured after a complete tartar emetic treatment.

(*b*) 4 discharged, after treatment with tartar emetic clysmata (infants, not allowing injections to be regularly applied).

(*c*) 1 discharged after treatment with emetine (serious arterio-sclerosis).

(*d*) 37 inadequately treated, viz., 2 on account of intolerance, 2 on account of disorders not due to the treatment and 1 on account of disorders due to the treatment. The others have untimely withdrawn from the treatment.

(*e*) 25 in polyclinical treatment on Monday, Wednesday, Friday.

(*f*) 25 in polyclinical treatment on Tuesday, Thursday, Saturday.

(*g*) 8 in clinical treatment.

(*h*) 3 not treated, viz., 1 on account of intercurrent disorders and 2 on account of serious bilharzia-cirrhosis of the liver.

(*i*) 6 died, 4 on account of serious bilharziasis of liver, lung and intestine.

(*j*) 109 untreated, will be gradually brought under treatment.

It is important to note that not one refused gratuitous treatment. The treatment has now become so popular that often Hindoos, male and female, sometimes with all their children, come long distances solely to be injected. In many cases they were satisfied to be treated when the examination of the fæces disclosed the presence of bilharzia eggs.

The results obtained with the intravenous application of tartar emetic are to be considered absolutely favourable. The fæces of nearly all the patients who have had five to six injections proved to be free from eggs with living miracidia, provided the treatment be not interrupted.

Only in a few cases the parasites or eggs were found more resistant, and ten to twelve injections were necessary to secure success.[1]

Of 24 patients long discharged, I was able to check the fæces for months (soldiers, personnel of the hospital and others), always with negative results.

[1] It is always necessary to find out whether an egg-case contains a miracidium or not. (Slight pressure on the cover-glass—eosin preparation.) Even after a successful treatment the egg-case, which is occasionally deposited in the intestinal wall, may appear in the fæces, sometimes accompanied by clinical symptoms (blood in the fæces).

[2] The parasites were very persistent in this case. Only after sixteen injections the fæces were shown to be permanently negative. The same patient suffered on August 18 from an attack of acute colitis with blood in the fæces. Examination revealed the presence of many empty egg-cases and no living miracidia; on September 8 a second attack. Examination disclosed eggs with living miracidia. The possibility of a re-infection is naturally not excluded.

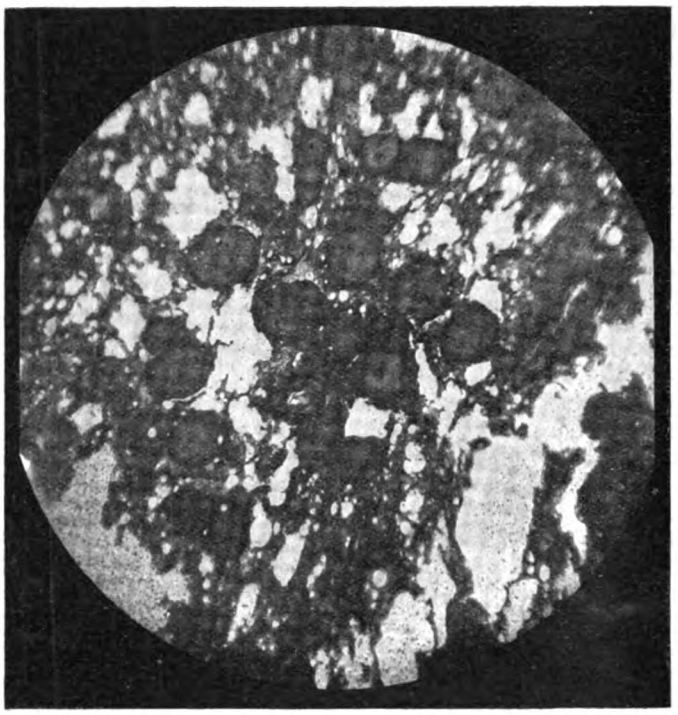

FIG. 3.—Photomicrograph of bilharziasis affecting lungs. *B. miliaris pulmonum.*

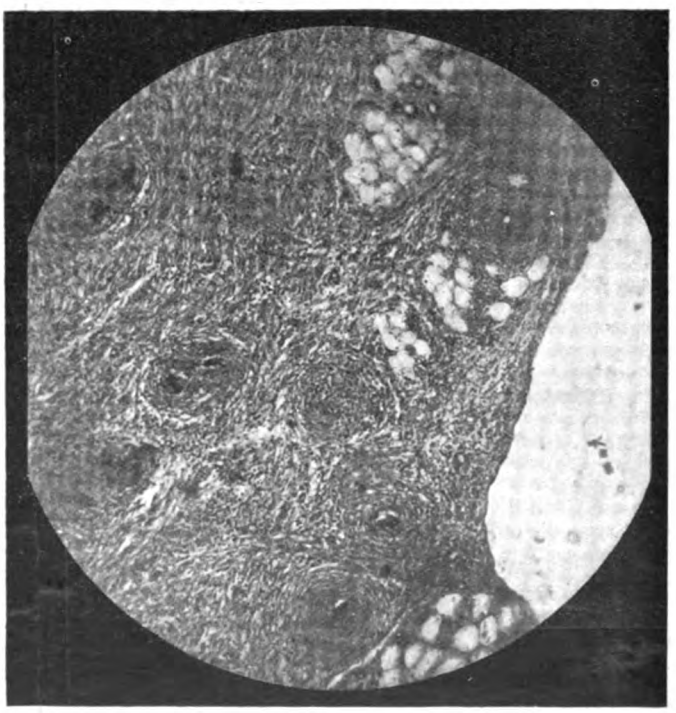

FIG. 4.—Photomicrograph of bilharziasis affecting the peritoneum. *B. miliaris peritonei.*

The duration of the control is as yet too short to allow a definite opinion to be expressed in connection with the applied treatment.

Judging from the negative results of all the controlling examinations, I believe that it will be proved later that all patients are permanently cured, i.e., that the applied doses and the subsequent concentration in the blood are certainly greater than the individually varying minimum necessary to kill all parasites and sterilize all eggs.

Different observations point to the fact that the necessary quantity of tartar emetic varies widely for different individuals, probably on account of the longer or shorter circulation in the blood.

The more ready excretion, the subsequent lower concentration in the blood would then explain the absolute absence of by-complication in children.

The less ready excretion and the subsequent higher concentration in the blood would then make intelligible the unfavourable results in the case of patients whose treatment had to be untimely stopped through interfering disturbances.

The question therefore arises, whether it may be considered right to inject all patients with the dogmatic dose of 200 *c.c., especially since tartar emetic cannot be looked upon as a harmless remedy.*

It would have been much better if a proper account could be made of the individual reaction.

The examination of the fæces does not afford the slightest warrant. In cases of rectal bilharzia (in total the minority) the examination of the rectum by means of the speculum or rectoscope is most important (Christopherson, by correspondence), but the mass-extermination of the parasites need not run parallel with the eventual curing of the local process.

About the complement-fixation reaction of Fairley becoming negative in cases of cured patients, I have no experience. According to Fairley, however, this reaction bears a similar relation to bilharziasis as does the Wassermann reaction to syphilis (*Lancet*, June 14, 1919), so that this also is not adequate for the immediate control of the dose of the tartar emetic.

It is therefore desirable to find a criterion, indicating for each patient the minimum therapeutic dose.

The regular examination of the blood-picture of a large number of bilharzia patients before, during, and after treatment has brought to light something that probably will enable us to determine this individually varying minimum.

It is proved that during the treatment—after a number of injections had not shown any influence—the already existing eosinophilia (+ 20 per cent.) increases to 50 to 80 per cent., only again to decrease, some time after the treatment has finished, to far below the original percentage.

A preliminary investigation has brought to light something to the same effect in the treatment of filariasis, but only when microfilariæ are present in the blood.

I am inclined to explain this eosinophilia as a phenomenon due to anaphylaxy, arising at the moment when a large number of parasites are destroyed.

A considerable quantity of "dead," extraneous "albumin" enters into the circulation of patients already possessing antibodies against that same extraneous albumin, in consequence of a preceding spontaneous destruction of a few parasites.

It is even probable that this supposed anaphylaxy gives an explanation of the fever, ague, itching urticaria, exanthema, local one-sided œdema, &c., so often observed during the treatment.

It is therefore highly inviting to speculate on the basis of a curve representing the eosinophilia after each injection or at the end of every week, on the possibility of the moment when the largest number of parasites are destroyed.

Further investigation in this line will show whether this supposition is justified or not. It should then be carefully investigated whether (with the aid of the regular control of the eosinophilia) the dogmatic dose of 200 c.c. (according to Christopherson 30 gr.) can be replaced by an individually varying minimum that may be smaller or larger, but which at any rate guarantees an absolute cure.

The relapses so often mentioned in the literature and arising after the application of the official dose will then soon belong to the past.

When the aforementioned precautions are considered, we possess in tartar emetic a remedy that can be applied without fear, in a sufficient dose that, in conformity with the statements in the relative literature from other countries, cures bilharzia parasitism and ends the sufferings caused by bilharziasis.

The eventual anatomical lesions of the organs and tissues could then later on be treated, often with success, therapeutically or surgically.

It is therefore of primary importance that the carrier of bilharzia shall not delay or avoid the treatment until he becomes a serious bilharzia patient. The same may be said of a large number of filariasis patients, frequently met with in this country. The bilharzia—like the filaria carrier—can always be cured. The bilharzia—like the filaria patient—often not.

It is therefore necessary that tartar emetic injections should be as popular in the tropics as are neosalvarsan injections. The time should come when the Creole, Hindoo and Javanese will ask for tartar emetic injection as he now asks for neosalvarsan.

But to attain that end great circumspection is recommended in treatment, especially with tartar emetic, the results of which are less perceptible and striking than in the case of neosalvarsan.

It is preferable to apply one injection less and have a satisfied patient than to have a discontented lamenter with the full dose. It is better not to inject an infant than to cause cellulitis which will be demonstrated at home to friends and acquaintances.

It is desirable not to treat a bilharzia patient suffering from ankylostomiasis at once, but to cure his anæmia first.

The tartar emetic injection, when applied with the necessary discernment and tactfulness, will in the long run enjoy the popularity indispensable in combating diseases of the people such as bilharziasis and filariasis.

The Treatment of Leprosy with Derivatives of Chaulmoogra Oil (H. E. Hasseltine, *U.S. Public Health Bulletin*, July, 1924).—Treatment of leprosy with the ethyl esters of the fatty acids of chaulmoogra oil as the main therapeutic agent, extending over a period of slightly over two years, has resulted in the parolling of 23 per cent. of all cases as no longer a menace to the public. Two of those parolled have relapsed. Sixty per cent. of those remaining in segregation have been definitely improved, 31 per cent. remain practically stationary after a slight initial improvement, and 8 per cent. have grown worse. Of the patients under treatment six months or longer, 69 per cent. of the incipient, 37 per cent. of the moderately advanced, and 9 per cent. of the advanced cases have been parolled. Of those remaining in segregation (under treatment six months or longer), 91 per cent. of incipient cases, 82 per cent. of moderately advanced cases, and 39 per cent. of the advanced cases have improved. The percentage of deaths in the three stages has been 0·0, 1·5 and 14 respectively.

The use of the mixed ethyl esters of the fatty acids of chaulmoogra oil intramuscularly has given better results than the esters of single acids. The addition of iodine to the mixed esters is of value in that it reduced local irritation and discomfort. In the author's experience the butyl esters have no advantage over the ethyl esters of the fatty acids of chaulmoogra oil. The ethyl esters may be used intravenously, but it is believed that the intramuscular injection is more efficient. The greatest advantage of the ethyl esters of the fatty acids of chaulmoogra oil over the crude oil and emulsion thereof for injection purposes, lies in the fact that the pain and reaction following the esters is so much less that practically all patients will take injections regularly over long periods of time. With crude oil preparations, only a small percentage of patients will continue injections a sufficient time to receive any benefit therefrom. The mixed ethyl esters of the fatty acids of chaulmoogra oil containing 1 per cent. of iodine have proven the best therapeutic agent in leprosy that has been used at the station at Kalihi, Honolulu, Hawaii, up to the present time.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE MOSQUITOES OF EGYPT.

EXCEPT for a few isolated records by early collectors the first systematic account of mosquitoes captured in Egypt appears to be that of Becker who collected Diptera generally in Egypt in 1902. He recorded only five species of Culicidæ, of which three were described as new. From time to time Willcocks collected a considerable number of mosquitoes, many of which were sent to Theobald for determination of the species. Gough in 1914 records seventeen species of Culicidæ from Egypt, of which twelve (possibly thirteen) were regarded as being genuine Egyptian species. A certain number of mosquitoes were also collected during the War by officers of the R.A.M.C., Lieutenant P. J. Barrand, Entomologist to the E.E.F. publishing a short "Guide to the Identification of Anophelene Mosquitoes of Syria, Palestine and Egypt," most of the information on Egyptian mosquitoes having been supplied by Mr. G. Storey of the Entomological Section of the Egyptian Ministry of Agriculture. In 1918 Mr. Storey commenced a survey of Egyptian mosquitoes which unfortunately was never completed owing to pressure of other work. Eighteen species were recorded by him, including sixteen genuinely Egyptian species, of which three had not previously been recorded from Egypt. The death of Mr. Storey in 1922 is much to be regretted as a large number of his records of the localities and breeding places of mosquitoes which would undoubtedly have been of the greatest interest and value appear to have been lost. A Blue-book[1] containing a report by the Senior Entomologist to the Egyptian Ministry of Agriculture now appears as the outcome of a request by the Anti-Malaria Commission of Egypt that the Entomological Section of the Ministry of Agriculture would undertake a Survey of the Mosquitoes of Egypt. This survey was commenced in January, 1924. Every effort has been made to make the survey of the Delta, the Fayum and the Nile Valley as complete as possible, but with the limited time it has not been possible to study the desert regions with the same detail.

Twenty-two species of mosquitoes have been recorded as found in Egypt up to the present date, and these are grouped according to the present volume as follows:—

Mediterranean species, comprising *Anopheles superpictus, Uranotænia unguiculata, Theobaldia longeareolata, Culex tipuliformis, C. laticinctus* and *C. perexiguus.*

European species, comprising *Ædes caspius* and *A. detritus.*

North African Desert species, comprising *Anopheles sergenti, A. multicolor, Culex pusillus, C. pluvialis, C. deserticola* and *C. sinaiticus.*

Almost cosmopolitan species, comprising *Culex pipiens* (originally from the Palæarctic region) and *Ædes argenteus* (originally from the West Indies?).

Spread from Ethiopian region—*Anopheles mauritianus, A. pharoensis, A. rhodesiensis, Culex quasigelidus* and *C. laurenti.*

Spread from Oriental region—*Culex tritæniorhynchus.*

It does not appear easy to state authoritatively which parts of Egypt are most infected by mosquitoes

[1] "The Mosquitoes of Egypt." By T. W. Kirkpatrick, B.A., F.E.S., Senior Entomologist Minister of Agriculture, Egypt. Government Press, Cairo. 1925. Price P.T. 30.

at the present time. The Canal Zone, more especially the western shores of the Bitter Lakes, would undoubtedly have been given the premier position a few years ago. The remarkably successful work of the Suez Canal Company, however, between 1901 and 1903, completely stamped out all mosquitoes, and consequently all malaria, from Ismailia. Results, too, are already apparent from the drainage works now being carried out by the Egyptian Government, both at Qantara and places south of Ismailia. The Nile Valley, south of Cairo, can boast of a much smaller mosquito fauna, both as regards species and numbers, than of any other part of the watered area of Egypt. This is stated to be probably largely due to the system of irrigation, as the flooding of the basin lands in the autumn clears out a large number of breeding places. When the floods subside, however, many suitable breeding places are left, but many of these now contain fish, and the numbers of mosquitoes have been much reduced by the check in their breeding at a season of the year when otherwise it would have been proceeding rapidly.

The oases of the Western Desert now appear to be the most mosquito-ridden parts of Egypt, notwithstanding the drainage operations which have greatly reduced their numbers. A notable exception, however, is the immediate neighbourhood of Siwa Town, which has become practically free from mosquitoes since the introduction of fish into all the wells, ponds and drains. The small oases of the Eastern Desert and Sinai Peninsula, such as that of Ain Gedeirat, are also much mosquito-ridden. Next in order comes the Fayum, followed closely by the Canal Zone (except Ismailia) and the Wadi Tumilat. Next must be placed parts of the Delta in the neighbourhood of large salt marshes, where large uncultivated areas exist. Considerably better off are the intensively cultivated parts of the Delta, and finally the Valley of the Nile. In the towns of Ismailia and Siwa there is less likelihood of being bitten by a mosquito than in the desert.

With regard to seasonal prevalence, all those mosquitoes which are intrusions from the Ethiopian region are hot-weather species, and the true desert species probably æstivate as adults, unless, like the *Anopheles multicolor* and the *Culex pusillus*, they have become adapted to live in cultivated areas where there are suitable breeding-places throughout the year, in which case they are most abundant in late summer and autumn. Two of the Mediterranean species, *Culex tipuliformis* and *Theobaldia longeareolata*, are definitely cold weather breeders. There are also indications that *Uranotænia unguiculata* has two minimum periods of abundance, following shortly after the very cold and the very hot weather respectively, whilst the two species of *Ædes*, which have spread from Europe, are here near the southern limit of their range, and are more abundant in cool weather.

The borrow pits and the innumerable other pools and ponds which exist in all parts of the country provide the breeding grounds for the great majority of the Egyptian mosquitoes. In many parts of the country there are numerous old sakia pits and disused shallow wells. The former seldom or never breed *Anopheles*, though they provide an abundant supply of other mosquitoes, but old surface wells are often teeming with the larvæ of *Anopheles multicolor*.

It would not appear that mosquitoes are necessarily concomitant with agriculture in Egypt, except in the sparsely cultivated low-lying salt lands, where there are often pools of water during the whole year and numerous uncared-for stagnant drains, and in the case of rice cultivation. In the former efficient drainage would both enable mosquitoes to be controlled, and would bring under cultivation large tracts at present lying waste. The advisability of rice cultivation depends largely on the part played by *Anopheles pharoensis* in the spread of malaria, and it would be of little value to prohibit or restrict rice cultivation until attempts had been made to deal with all the other possible breeding places of this species in the neighbourhood. *Anopheles multicolor*, however, said to be the chief carrier of malaria, does not breed in rice fields. *Anopheles sergenti*, which carries malignant tertian malaria, breeds in the rice fields in the Western Oases and on the shore of the Bitter Lakes; it has not, however, yet been found in the rice fields of the Delta, and probably does not occur there.

F. E. T.

Annotations.

The Larval Trematode Infestation of the Fresh-water Molluscs of San Juan Island, Puget Sound (H. M. Miller, jr., *Washington University Studies*. Vol. XIII., No. 1, 1925).—A survey has been made of the larval trematodes infesting the fresh-water molluscs of San Juan Island, Puget Sound. In so far as the search for molluscs was thorough, each of the five habitats examined has a characteristic fauna, and a correspondingly characteristic larval trematode fauna, *Lymnæ stagnalis*, and three, and possibly more, species of small *Planorbis* yielded the greatest number and variety of trematodes.

About half of the larvæ found are furcocercous; seven species are new and two were found previously in Michigan. Because of the isolated position of the island, the few fresh-water habitats, and the limited vertebrate fauna, it is thought that San Juan Island offers particularly favourable conditions for the study of trematode life histories. This survey of the larvæ has been made as a basis for such investigations.

A Case of Pulmonary Moniliasis (A. Collard and D. Jaumain, *Bruxelles-Médical*, October 18, 1925). In this communication Collard and Jaumain record the first case of broncho-pulmonary moniliasis contracted in the Belgian Congo. It presented the characters or course of a case of pulmonary tuberculosis. Examination of the sputum, including in-

jection of a guinea-pig, proved negative for tubercle bacilli. Radioscopic examination also gave an image different from that of pulmonary tuberculosis. The apices and margins of the lungs were clear, but the central portions of the lung parenchyma showed a dense opacity with cavity formation. Bucco-laryngeal complications were present, giving the appearances of laryngeal tuberculosis. Treatment, including injections of oil of picot (iodoform, eucalyptus and creosote), intravenous injections of cacodylate of soda and the simultaneous oral administration of iodide of potassium, was inefficacious and the case terminated fatally. A monilia was obtained on culture which was pathogenic for the rabbit when injected intravenously or into the lungs, but was entirely without effect on subcutaneous or intraperitoneal injection. Further researches into the characters of the monilia are made the subject of a further communication to the Belgian Society of Biology.

Rocky Mountain Spotted Fever. Experimental Study on Tick Virus (R. R. Spencer and R. R. Parker, *Public Health Reports*, November 28, 1924).—In confirmation of earlier observations of previous workers, ticks of the species *D. andersoni* which have received the infection of Rocky Mountain spotted fever in the larval or nymphal stage retain it in the adult stage. A twenty-four hour incubation at 37° C. of unfed hybernating nymphs and adults infected as larvæ and subsequent injection of such ticks into guinea-pigs give a higher percentage of positive infection than the injection of similar ticks not incubated.

Infection of Rocky Mountain spotted fever in adult ticks subjected to winter temperatures (32° F. or below) may be demonstrated by the production of immunity in guinea-pigs following the injection of tick viscera immediately upon removal from cold temperatures, by a moderate but typical spotted fever following the injection of ticks after twenty-four hours incubation at 37° C., and by virulent spotted fever following tick feeding or the injection of ticks after feeding. Control adult ticks free from all infection do not produce death or illness in guinea-pigs by feeding nor by injection of such ticks after feeding. One infected adult tick may contain after feeding from 3,000 to 5,000 M.I.D. for a guinea-pig. Emulsion of infected fed adult ticks treated with 0·5 per cent. phenol will protect guinea-pigs against 1 c.c. of blood-virus. Nothing in the behaviour of blood- or tissue-virus is comparable to the changes observed in tick virus.

A Case of Spirochætosis Bronchialis (H. L. Heimann, *The Med. Journ. S. Africa*, July, 1925).—This constitutes the second of the "four cases of interest" of Dr. Heimann's paper. A married woman, aged 28, was seen in April, 1925. She had had a "cold" three months previously and coughed ever since. The cough was spasmodic and worse in the early morning, when she expectorated a thick, yellow sputum. There had been no hæmoptysis, no night sweats and no gastro-intestinal symptoms. She was three months pregnant. At various times there had been night fever. The general condition was good, though she had lost weight in the early stages of her illness, but had regained it. The physical signs in the chest suggested the diagnosis of pulmonary tuberculosis. Previous examinations of the sputum, both directly and by concentration methods, were negative for tubercle bacilli. Another examination showed *Bacillus friedländer*, streptococci and spirochætes, but no tubercle bacilli. An early morning specimen, after careful cleansing of the mouth, showed the presence of *Spirochæta bronchialis* in numbers. The pregnancy was allowed to proceed. Treatment consisted in the oral administration of liquor arsenicalis and sodium glycerophosphate and an autogenous vaccine prepared with the secondary invaders. Then intramuscular injections of sodium cacodylate combined with sodium glycerophosphate were given. The signs and symptoms disappeared and the patient has remained free from recurrence.

Melioidosis: A Disease of Rodents Communicable to Man (A. T. Stanton and Wm. Fletcher, *Bulletin Institute for Med. Research*, Federated Malay States. No. 5, 1924).—Melioidosis and tularæmia, two diseases which cause a large amount of damage, are of very limited distribution, especially the latter. Apart from one case in Singapore, melioidosis has been recognized nowhere except in the towns of Rangoon and Kuala Lumpur. As it is difficult to believe that the disease is confined within such limited bounds, the authors have written this paper to enable other workers to recognize the disease when they meet it. Melioidosis is very like glanders, and its symptoms vary according to the part or organ of the body affected. The true nature of the disease can be determined only by cultivation of the causative organism, *Bacillus whitmori*, from the lesions, or blood, sputum or urine. The organism has very marked specific characters, which have been described in detail by Whitmore (1913). Goats, guinea-pigs, rats and other rodents are very susceptible to the disease; domestic fowls are not. The characteristic lesion of melioidosis is a small, yellow caseous nodule which commences as a collection of polynuclear cells surrounded by a zone of congestion. By the time these nodules have become large enough to be visible to the naked eye, they consist of a mass of necrotic, caseous material containing a great number of chromatin fragments which are the remains of dead nuclei. The lungs are nearly always affected. The spleen is enlarged and frequently contains nodules and small abscesses filled with thick greenish-white pus. Melioidosis presents no cardinal symptoms upon which to base a diagnosis. Some of the most acute cases resemble cholera or plague; others resemble malaria, enteric fever or general tuberculosis. With two exceptions, every person known to be infected with the disease has died; of these two exceptions one recovered after a long illness, and the other

was still an invalid with abscesses, sinuses and chronic suppuration in the bones of his feet and legs, more than two years after the commencement of the malady.

Fractionation of Chaulmoogra Oil. (II) *Evidence of the Existence of a Highly Unsaturated Optically Active Acid* (R. Wrenshall and Arthur L. Dean, *Public Health Bulletin*, July, 1924).—The high boiling portions of the mixed fatty acids derived from commercial chaulmoogra oil contain, associated with chaulmoogra acid, a liquid acid of high iodine value. By systematic fractional distillation of the liquid acid residue after the removal of chaulmoogra acid by crystallization, fractions were repeatedly obtained with iodine values of 160 or higher. By applying the lead salt-ether method to highly unsaturated fractions a material was obtained with an iodine value of 168·3 by the Hubl method with a three-hour saturation period. By following the suggestion of Lewkowitsch and allowing a longer period the iodine value rose to 180·4. By catalytic reduction with hydrogen, dihydrochaulmoogric acid was obtained from this highly unsaturated acid. It is believed that this acid is a chaulmoogric acid with a second double bond and a formula of $C_{17}H_{29}COOH$. The work herein reported has been greatly facilitated by personnel and materials furnished by the Territorial Board of Health, Territory of Hawaii, and a generous donation which was used to procure special apparatus and other necessities for the advancement of the investigation.

The Treatment of Leprosy with Compounds of Antimony (H. E. Hasseltine and P. J. Gorman, *Public Health Bulletin*, July, 1924).—A trial of colloidal antimony in a group of ten lepers resulted in a very slight gain of strength of the hand-grip in anæsthetic cases, when tested by the dynamometer. However, a control group, not receiving antimony, showed almost as great improvement in this respect. No effect upon the lesions of nodular and mixed cases nor upon the number of acid-fast bacilli in the lesions was observed. From the limited experience gained from the observation of a small group, the authors feel that antimony compounds should not be used to the exclusion of chaulmoogra derivatives in the treatment of leprosy.

The Formol-Gel Reaction in Leprosy (H. E. Hasseltine, *Public Health Bulletin*, July, 1924).—The formol-gel test has been applied to serums of 195 cases of leprosy and the same test, incubated at 37° C., was applied to the serum of 170 of these cases. The test was read at the end of twenty-four, forty-eight and seventy-two hours. At room temperature, of 195 serums tested, 118, 137 and 154 showed positive results at the end of twenty-four, forty-eight and seventy-two hours respectively. At 37° C., of 170 serums tested, 126, 154 and 161 showed positive results at the end of twenty-four, forty-eight and seventy-two hours respectively. The test was applied in 49 cases of anæsthetic leprosy, 91 cases of nodular leprosy, and 55 cases of mixed leprosy. At the end of twenty-four hours the anæsthetic cases gave positive results in 45 per cent., the nodular cases in 64 per cent., and the mixed cases in 69 per cent. Correlation of the results of the formol-gel and Wassermann tests shows that they have a tendency to agree, especially in those giving highly positive Wassermann reactions. On the other hand, at least 50 per cent. that gave a negative Wassermann reaction, gave a positive formol-gel reaction. The application of the test to 14 supposedly normal persons, all of whom, with one exception, showed no evidence of a positive Wassermann reaction, gave a negative result when the test was set at room temperature. When set at 37° C. 3 out of 14 showed a weak positive formol-gel test at the end of twenty-four hours, and at the end of seventy-two hours 10 of the 14 showed some degree of positive result. A greater proportion of positive formol-gel reactions are found in advanced cases of leprosy than in incipient or moderately advanced cases. The formol-gel reaction cannot be considered a reliable serum reaction for the diagnosis of leprosy, but may have some value as a corroborative test.

The Wassermann Reaction, Kolmer's New Complement-fixation Test, and the Kahn Precipitation Test in Leprosy (H. E. Hasseltine, *U.S. Public Health Bulletin*, July, 1924).—There apparently is a tendency to the formation of some reagin in the serum of lepers that will fix complement in the presence of the usual Wassermann antigens, particularly with cholesterinated alcoholic extracts. This tendency shows least when acetone insoluble lipoid antigen is used. It is most noticeable in the nodular type of leprosy and least observed in the anæsthetic type; and in all types it is seen more frequently in the advanced cases. The antigen devised by Kolmer, and used in his new complement-fixation test, gives satisfactory results, and it is believed that the Kolmer test is the preferable procedure in determining syphilis in lepers. Although work with the Kahn precipitation test has not been entirely satisfactory thus far, it is believed that this test will prove a valuable one in determining the presence of syphilis in leprous subjects.

The clinical diagnosis of syphilis in leprous subjects in Hawaii is extremely difficult. In some cases syphilis seems very effectively masked by leprosy. The Wassermann reaction cannot be considered an aid in the diagnosis of leprosy. A large number of undoubted lepers give a negative W.R. even when highly sensitive cholesterinated antigen is used. In the differential diagnosis of leprosy and syphilis in doubtful cases a positive W.R. with acetone insoluble lipoid, or the Kolmer, antigen is strong presumptive evidence of syphilis, and in the absence of definite evidence of leprosy such patient should be given antisyphilitic treatment before he is declared a leper. Lepers who give a positive

blood W.R. have a graver prognosis than those giving negative W.R. A positive W.R. against an acetone insoluble lipoid antigen, or against the Kolmer antigen, is ample evidence to justify the rigorous use in leprous subjects, of antisyphilitic measures, and such measures should be checked by serum tests during and after such treatment.

Bilharziasis of the Female Genital Tract (R. W. B. Gibson, *Medical Journal of South Africa*, September, 1925).—It was formerly believed that bilharziasis was much commoner in men than in women, but recent work has shown that the difference is not due to sex, but to other circumstances. The researches of Mrs. Ellgood in Egypt, of Turner in Johannesburg, and of Howard in Nyasaland have established the fact that women are more commonly infected than was formerly believed; and Gibson, in recording a case of bilharzial affection of the Fallopian tube complicating a tubal pregnancy, states that it is probable that incidence of genital bilharziasis in the female is much commoner than the published reports of cases would suggest. The more superficial parts of the genital tract in women appear to be most commonly affected. At the vulva papillary growths or deep ulceration results. The papillary growths often assume considerable proportions and closely resemble venereal warts in appearance. The ulceration may cause destruction of the hymen and clitoris and may completely surround the urethral orifice. Papillary growths at the edges of the ulcers may simulate carcinoma. In the vagina the mucosa and submucosa are thickened with friable tissue which is easily eroded, with resulting hæmorrhage and even vesico-vaginal fistulæ. In the cervix the disease takes the form of polypoid excrescences or small fibro-adenomatous tumours, and closely resembles carcinoma. Bilharzial disease of the body of the uterus does not appear to have been recorded up to the present.

The uterine appendages would appear to be rarely affected. Sumners, in Egypt, recorded such a case in a young child in whom a mass of tissue was found involving the ovary and upper edge of the broad ligament, on which *Bilharzia* ova were found on microscopic examination. Gibson now records a case of bilharzial affection of the Fallopian tube complicating tubal pregnancy in a married woman aged 25, who, four months after marriage, consulted her doctor in Johannesburg because she had missed one menstrual period. The early part of her life had been spent in Durban, and there had never at any time been any of the usual symptoms of *Bilharzia* infection. She presented the signs and symptoms of extra-uterine pregnancy, and this diagnosis was confirmed at operation. The ovum occupied the ampulla of the unruptured tube, and there had been a fair amount of bleeding into the peritoneal cavity through the abdominal striæ. The distal part of the tube was greatly thickened and the mesosalpinx was filled with irregular masses of soft fibrous tissue. The tube and broad ligament were removed, and on microscopic examination showed the presence of terminal-spined *Bilharzia* (*Schistosoma hæmatobium*) ova in great numbers. It would appear probable that in this case the bilharzial lesion was responsible for the arrest of the fertilized ovum and the development of the tubal pregnancy.

Tryparsamide in Syphilis (Wm. C. Menninger, *Medical Journal and Record*, September 16, 1925).—Tryparsamide, an arsenical compound containing 25·32 per cent. arsenic in the pentavalent form, has shown itself to be an effective therapeutic agent in cases of trypanosomiasis. Its use in the treatment of syphilis is based more upon its power to penetrate nervous tissue, rather than its spirochæticidal power. From clinical studies, it is found advantageous in the treatment of neurosyphilis, particularly general paralysis, but is ineffective in primary and secondary syphilis, and in tertiary syphilis in which there is no involvement of the central nervous system. The method of treatment usually advised is in either two- or three-gramme doses, dissolved in 10 c.c. of sterile water, given intravenously once a week for a course of eight to twelve doses. A rest period of one to three months is given between courses. One or more courses may be given. The only serious disadvantage is encountered in visual disturbances, which occur relatively infrequently, and need not cause permanent damage if careful attention is given to the dose of the drug.

Correlation of the Sulphite Reduction Test with other Tests in the Bacteriological Examination of Water (W. J. Wilson and E. M. McV. Blair *Journal of Hygiene*, October, 1925).—The results of these investigations are: When 40 c.c. of water samples are added to an equal volume of a glucose-sulphite-iron-agar medium, the number of dark sulphide colonies varies from 0 to several hundreds, according to the degree of contamination of the water. (*a*) Very pure water, whether surface or well, shows none. (*b*) A potable water should not show more than 4. (*c*) Sand-filtered water should not show more than 1.

There is a fairly close agreement in the results of the *B.coli* and the reduction tests. Where *B. coli* is found in small amounts of water, of which 40 c.c. contain no reducers, it has been found that the coliform bacilli are not true *B. coli*, but that they are allied to *B. aerogenes*, as shown by Koser's citrate test. The dark colonies can be classified according to their size into large, medium, small and tiny. *B. welchii* usually forms a large or medium colony. A selective medium for streptococci is described. The sulphite medium can be applied in attempts to isolate typhoid bacilli from water or stools, the addition of brilliant green in 1 in 1,000 to 1 in 20,000 inhibiting the growth of anaerobes whilst allowing that of *B. typhosus* in the sulphite medium. The results obtained in the examination of 252 samples of water by the *B. coli* and sulphite reduction tests are correlated.

ARCHIVES DE L'INSTITUT PASTEUR DE TUNIS.
Tome XIV, No. 3, 1925.

Note on the Existence of Hymenolepis nana in Tunis (A. Espie).—During the last two years investigation has been made on the intestinal parasites of natives of Gafsa. Of 396 specimens of fæcal matter examined, twenty-eight were found to contain eggs of *Hymenolepis nana*. They never surpassed 68 to 70 microns in length. 550 specimens of natives and fifty of Europeans in the region of Sfax were also examined, with the result that the presence of eggs identical with those found at Gafsa was detected thirty times. Most of the stools examined were from children; no adult worms were found. *H. nana* has been found by several authors in North Africa, but it is believed that this is the first time its presence has been detected in Tunis. This parasite causes various disorders in the human organism: gastro-intestinal troubles, nervous symptoms, &c. Europeans complain of these troubles, but the natives do not seem to feel any effects. Although these investigations show the percentage of infestation to be high, it is thought that *H. nana* is harboured by a greater number of inhabitants of Tunis than it was possible to examine.

Experimental Immunity of the Dog in Kala-azar: Evolution of the Malady in Dogs: Natural Immunity and Immunity by the First Natural Attack (Ch. Nicolle and Ch Anderson).—The following conclusions are drawn from this paper: A first attack of experimental kala-azar, of canine or human origin, gives immunity to the dog vis-a-vis an injection strongly virulent for the dog. It is probable that a first natural attack of kala-azar also leaves such immunity, and it is also possible that consecutive immunity to either natural or experimental disease is not only of a transitory duration. There has been no proof of the existence of natural immunity to kala-azar in the dog. Different dogs, inoculated with either canine or human virus, do not present the same infections. Very often experimental kala-azar is cured after a duration of some months, during which the presence of numerous *Leishmania* can be detected in the bone-marrow or in the liver. Fatal cases occur where the animal is either severely infected or in a cachectic state after the infection is cured or on the way to being cured. To preserve virus in dogs four to six animals should be inoculated, and passage of the virus carried out on animals known to be well infected towards the second or third month of inoculation. It is believed that the evolution in the dog of natural kala-azar does not differ from experimental kala-azar.

Experimental Researches on the Mode of Transmission of Kala-azar (Ch. Nicolle and Ch. Anderson).—These experiments were carried out with the aim of proving whether the bug plays a rôle in the transmission of kala-azar. Bugs frequently feed on the blood of dogs and suffer no effects and continue reproducing. In this way they are capable of transmitting virus from dog to dog and from dog to man, but experiments prove that they do not play the rôle of agent in transmitting kala-azar.

Note on Paramelitensis (Et. Burnet).—By agglutination, confirmed by the absorption of the agglutinins, two groups of *melitensis-abortus* can be distinguished, classed as group I and II; group II corresponds to *paramelitensis*. *Paramelitensis* possesses the characters described by Bassett-Smith; it is agglutinable by the non-specific serums; it does not produce agglutinin in the rabbit, but spontaneously agglutinates in peptone water. *Paramelitensis* cannot be classed with the non-agglutinable *melitensis*. The parasite is not rare; it is partly responsible for the relapses of the agglutinant reaction in Mediterranean fever.

Three Cases of Kala-azar in the Adult in Tunisia (Et. Burnet, F. Masselot, F. Calmida and G. Ortona).—The first case reported of kala-azar in Tunis was observed by Laveran in 1904, and the second in 1906 by Nicolle and Casuto. Since 1904 to the end of 1924 sixty-seven cases have been reported, but not one of these cases was an adult. All the patients were between five months and nine years of age. Since the beginning of 1925, however, three cases of kala-azar have been observed in adults. The first of these three was reported in a woman in Paris who lived at La Goulette. The other two were observed in the hospital at Tunis. In none of these three cases has the origin of the malady been determined.

I.—Introduction.

The study of parasitic filtrable viruses is not without importance for medical men in the tropics, for quite apart from the interest arising from universal epidemics caused by these micro-organisms, several diseases of warm climates, whose pathogenesis is still obscure and whose sudden appearance, rapid spread and gradual but equally unexpected disappearance have not got beyond the stage of conjectural explanation, may yet yield a solution of the riddle by an increased knowledge of these minutest among the minute harbingers of disease. In fact it is quite possible that tropical diseases whose ætiology and pathology appear to be a concluded chapter and a finally settled question, may be discovered to originate in the first instance through the action of a "virus."

In this as in many other epidemiological matters we have to refer to L. W. Sambon as a torchbearer, for I remember that about fifteen years ago in one of his lectures at the School of Tropical Medicine at the Albert Docks, in explaining the well-known lack of cyclical development of the parasite of malaria in the anopheles of certain regions in Italy, he suggested it might well be due to the presence of a minute germ, a "hypo-parasite" as he called it, preying on the plasmodium. At the time this appeared a bright idea and nothing more, but the discovery by F. W. Twort in 1915 of the lysin-body invading and dissolving *B. coli* has brought this suggestion of Sambon well within the range of concrete realization.

It may be recalled that L. W. Sambon has published two epidemiological studies of cancer in this Journal, one on June 2, 1924, the other February 2, 1925, in which he definitely states that cancerous growths developing as a result of helminthic infestation are very probably due to ultramicroscopical viruses; and accordingly it has been objected that ignorance of the causation of cancer is being obscured by the exorcism of powers we know as little about. This is not so, as the following pages will attempt to prove.

In the main this paper was begun at Robben Island, in 1913, at the instigation of Sir Patrick Manson, who at that time was visiting South Africa. Interrupted by other work it was taken up again in 1917, following numerous filtration experiments performed at the Middlesex War Hospital at Napsbury, again abandoned and eventually completed in the present form during 1925.

II.—General Properties of Filtrable Viruses.

True filter-passing viruses differ in many important properties from pathogenic protozoa and bacteria, though admittedly superficial resemblances to the former or latter can at times be detected; the resemblances, however, not being of sufficient importance to warrant the inclusion of parasitic filter-passing viruses in an intermediate phylum like that of the Protista; it should however be noted that certain spirochætal bodies (*Leptospira*) are apt at times to behave like microplasms.

They are invisible or ultramicroscopic—but the two terms are by no means interchangeable. They are to a certain point invisible with ordinary microscopic methods, but in many cases this invisibility requires qualification, as in filtrates from virus-infected material one can often detect numerous very minute granules by means of a good dark-ground illuminator. Some of these are possibly small agglomerations of virus, but they cannot be differentiated with certainty from other similar pulviscular bodies which are accidental and incidental contaminations of every filtered fluid. Therefore it would be more correct to call them morphologically indistinguishable or unrecognizable.

In time, by means of photomicrography with short-waved ultra-violet rays, dark-ground illumination, and other means, we shall be able to ascertain more about the morphology of invisible viruses, but in this matter at the present moment we are in the analogous position of investigators about fifty years ago who were studying "zymotic" diseases. They found undeniable bacteria everywhere, and in everything, and did not possess our methods of artificial culture or knowledge of agglutination and immunity, enabling them to differentiate a relatively harmless saprophyte like *B. coli*, or a simple dermophytic streptococcus from a dysentery or typhoid bacillus, or again from a virulent hæmolytic coccus.

Thus invisible or ultramicroscopic does not really characterize the class—not only because in certain stages the viruses of rabies, small-pox, vaccinia, trachoma, verrucæ, &c., are clearly visible as chlamydozoic bodies, but in addition because definite filter-passers such as the virus of pleuro-pneumonia are just within the range of microscopic visibility, whilst others again, though visible, are not clearly recognizable.

Filtrable or filter-passing denotes of course a property which is also a function of size in certain stages—in other words, means that the germs constituting the virus are smaller than certain bacteria,

but not smaller than all bacteria. Filtrability is shared with many spirochætal bodies and possibly certain stages of pathogenic protozoa ; and as filtration is in reality a technical short cut to enable us to separate bacteria from certain liquids, or obtain cell-free fluids, it does not select or sift virus bodies from other corpuscles of the same or smaller size which may be or may not be of a bacterial or even protozoal nature. Under the circumstances this criterion is not applicable for the purposes of classification or nomenclature.

Other properties equally important have been observed and studied, among which may be mentioned the peculiar and distinctive affinity or predilection of certain filter-passers for the cells of one tissue and practically that tissue only. Some protozoa (*Toxoplasma, Coccidia*) show this tendency, but not to such a marked extent in every case—and bacteria can be said on the whole to be fairly universal in their choice of sites for multiplication, but preferring an extracellular situation and thriving in fluids. It is true that variations within certain limits are discernible in filter-passers ; but considering the phylum as a whole one finds rabies showing a predilection for the central nervous system, though also present in salivary glands ; vaccinia for the epidermis, though the pustules appear to originate by a lesion of the capillary endothelium, and a localization in the nervous system is not unknown ; foot-and-mouth disease for the mucous lining of mouth and eyes, though evidently attacking the subunguial teguments of the hoofs ; trachoma, the conjunctivæ, inner surface of the eyelid, but a very similar virus is capable of multiplying in the urethra, and so forth.

This predilection is not an artificial distinction, such as might result by considering the gonococcus to have a specific attraction for the cells of the urethra, but is experimentally and microscopically recognizable by numerous observations which show, to take the oldest example known, that one gets the highest percentage of successful inoculations with rabies by intradural injections into the brain substance—if perhaps the practice of vaccination does not give a much older and better known confirmation of the general rule.

The production of chlamydozoic or strongyloplastic bodies in the tissues invaded is also a fairly constant appearance, which has given rise to much controversy. It is true that by various toxic and irritative influences one can bring about the production of very good imitations of Negri's or Guarnieri's bodies ; but to make use of a clinical similitude, the development of miners' phthisis through silica dust does not invalidate the claims of the tubercle bacillus as the cause of consumption of the lungs, and in the same fashion artefacts resembling the bodies found in many filter-passing diseases do not detract from the diagnostic value of Negri's bodies or the scientific interest of similar corpuscles found in many virus diseases of man and animals.

How do viruses generally bring about pathological appearances and symptoms ? It is well known that bacteria may do harm by massive multiplication (plague, lepra, anthrax), or elaboration of toxins (tetanus, tubercle), whilst protozoa more usually damage by abstracting cellular essential eleme (example : malaria), or inducing irritative changes capillaries of the brain (trypanosomes in sleep sickness), or again inducing the multiplication of cells they have settled in (kala-azar).

Viruses appear to injure by extensive intracellu multiplication—thus abstracting essential metab products from the nucleus and protoplasm and a causing necrosis by pressure. This is the explanat of the peculiar frothy, vacuolated or cytolyzed appe ance of epithelial cells in some skin conditions of m and animals—and also that of bacteria invaded Twort's bacteriolysin.

A toxic action of filter-passers no doubt exists, b is difficult to prove conclusively, as separation filtration or centrifugalization is not an easy matte

Adsorption or surface attraction phenomena pla great part in the bionomics of viruses—they complic in a disturbing fashion all filtration experiments w kaolin or porcelain filters ; in addition it explains h contrary to what occurs in bacteria in a generali infection the blood corpuscles appear to contain virus and not the serum ; the erythrocytes a leucocytes can then usually be washed free of virus

In conclusion one can surmise that they repres an ubiquitous, extremely simple form of living mat or protoplasm. It is true that, notwithstandi insistent search by Twort and others spreading o many years, it has not been possible to obtain a evidence of saprophytic or free-living viruses ; b since the principal method of detecting their prese consists in recognizing their pathogenic properties plants or animals (and we may also include bacte it is easy to explain the negative results of the sear It is of course understood that ordinary filter-passi bacteria are fairly common in various situation minute short spirilla which easily pass a Berkefeld a at times present in the fæces of guinea-pigs ; a fr living leptospira which is also filter-passing has be observed by Hindle (1925), and a very minu anaerobe by Holman and Krock (1925), in additi to Borrel's *Micromonas mesnili*, which is consider to be a filtrable protozoon.

A saprophytic filter-passer would be, however, n only extremely minute, but might make its presence absence recognizable by some enzyme-like action whi would be active after multiplying in infinitesim dilutions of a suitable medium ; and indeed Twor lysin approaches these conditions to a remarkal extent.

It is no idle hypothesis to surmise that viruses a not only extremely minute particles of protoplas with the simplest imaginable structure compatib with life—that is the faculty of selective assimilatio secretion and with the power of successive, almo limitless multiplication—but that also they ha hardly differentiated into cellular components, nucle and ectoplasm, and therefore they are extreme delicate and subject to damage by outside influenc when isolated ; the chlamydozoic mantle or shell bei accordingly a necessary protective covering suppli by the nucleus of the cell-host, for we do know th when included in cells they are fairly resistant.

The undifferentiated protoplasm explains the

ited assimilative powers, of which their selective tracellular position is but an expression, and also e need of abstracting nutrient materials which are eady suitably prepared for protoplasmic assimilation. the circumstances it is quite possible that prophytic or free-living microplasms cannot exist art from a suitable supply of ready digested and aborated albuminous substance, such as usually is ly found within a living cell.

A simple protoplasmic aggregate of molecules would so possess the quality of binding or incorporating elf with the protoplasm of the cells more intimately an a corpuscle with an ectoplasm. As a matter fact many viruses require not only mechanical ushing of their cell-host or hydrolysis, but also aceration or digestion with trypsin before they can even partially isolated from the protoplasm which rbours them—and even then one may doubt if the ocess is complete.

When discussing the properties of microplasms it is cessary to consider a peculiarity which, though esent in an analogous but restricted fashion in cteria and to a greater extent in certain protozoa, es not exactly correspond in all particulars. This is e fashion in which a microplasm will remain mpletely in abeyance, innocuous for prolonged eriods during which it gives rise to no symptoms, nd then suddenly, usually as the result of irritative timulus, produces definite recognizable pathological lterations. The expression "latency" covers the eriod of innocuous permanence, a condition well known in gonorrhœal infections, and also malarial diseases, but in these instances one is the result of minute anatomical conditions, the other the outcome f encysting. But a more accurate comparison would e given by the conditions arising in cerebro-spinal eningitis, where the micro-organism causing the isease is found as a harmless denizen of many aso-pharyngeal cavities, and so neither buried or capsulated.

In conclusion, for the reasons enumerated above one ntures to suggest the name Microplasm for the rms commonly known as invisible filter-passing ruses, a phrase which is a standing contradiction of st in every one of its terms.

One can state that it is only a simple question of me, craft and skill which will enable us in the ture to classify microplasms according to their orphology—and bionomics—in common with other rms of life, but for the present we perforce must do on the unsatisfactory basis of properties which ve so far been observed and that, possibly, but ompletely.

III.—Virus Diseases of Bacteria (Twort's Bacteriolysin).

In correct chronological sequence Twort's bacteriolysin would be placed among the viruses discovered in the second decade of this century; but as it presents numerous points of interest, is comparatively easily investigated, and has indeed been most extensively studied, it will be considered first, especially as it attacks in a specific and selective fashion cellular elements which are placed low in the scale of animate Nature. In addition the laws governing the action of the lysin and reaction of the bacterium are comparatively simple, and lead to an understanding of the more complicated problems resulting from the intricate processes involved in "virus" diseases of plants and vertebrates.

It is true that the "virus" or particulate nature of the bacteriolysin is fiercely contested by Bordet, Gratia, Ciuca, Rhode and many other Continental and British investigators, who consider the lysin to be an enzyme produced by the bacteria; but this can be said without excessive bias, that if Twort's bacteriolysin is an enzyme, not only it belongs to a new class of its own, but in addition behaves in a fashion indistinguishable from that of a virus akin to that of mosaic disease, but instead specific for certain bacteria.

An enzyme which is capable of multiplying *ad infinitum* given a suitable medium—certain living bacterial cells—is surely a curiosity of the first order, and therefore the subject will be again discussed later on in this chapter.

In the *Lancet* of December 4, 1915, pp. 1241-3, F. W. Twort published the discovery of his filter-passing bacterial lysin, though the work leading up to it had lasted over two years. The original paper gives in clear and unmistakable language the first complete account of an important discovery which has since been most extensively investigated without appreciably adding to the essential facts first described.

F. W. Twort found that by filtration through finest porcelain filters (Doulton White) he could separate from certain young cultures of micrococci, originally isolated from vaccinia lymph, a peculiar virus or enzyme which not only totally inhibited the growth of this micrococcus on agar but attacked young cultures of this bacterium and dissolved them into minute granules which stained a reddish hue with Giemsa.

A similar substance was obtained by filtration from other bacteria of the typhoid-coli group, and it was then found that the virus:—

(1) Was strictly specific for certain definite groups of bacteria from which it originally had been isolated and could not be cultivated apart from them; that is, a staphylococcus bacteriolysin had no action on streptococci, *B. coli*, yeasts, tubercle bacilli, &c., nor would multiply on their cultures.

(2) The virus could not thrive on dead bacteria, or in any known artificial culture medium if free from suitable living bacteria.

(3) Heat above 60° C. for an hour destroyed it, though it would retain its activity when emulsified and heated to 52° C.

(4) It could be kept for six months or even longer in an active state *in vitro* and would then again attack its specific bacterium.

(5) Not all strains or even individuals of the same bacterium were accompanied by this peculiar virus, for by plating one could obtain bacterial streaks which showed no signs of dissolution. Other colonies on the same plate might perhaps show a few isolated clear

spots. The virus could then only be obtained from spots which showed bacteriolysis.

(6) Occasionally the lysin appeared to arise spontaneously in pure stock cultures.

(7) It could be propagated through very great dilutions (one to millions) if incubated on agar with its accompanying bacterium, and could then be indefinitely transmitted from culture to culture of this bacterium.

(8) Laboratory animals inoculated with the filtrate in various fashions did not develop any pathological symptoms, nor was the substance recoverable from their body fluids.

F. W. Twort later discovered that specific antibodies could be produced in animals by the injection of the filtrate, but even now (1925), does not consider that the possibility of its being an ultramicroscopic germ is proved, though he admits it might almost be considered as an acute infectious disease of micrococci and thus be a virus.

Later researches by others can only be considered in the light of confirmation, amplification or completion of these fundamental experiments, for previous observations on the bactericidal properties of river water, &c., belong to a different order of ideas altogether.

Numerous investigations of the same subject were begun in 1917 by d'Herelle and his collaborators and also by different experimenters, and it was then found that the bacterial lysin could remain latent in bacteria for a few generations and then make its reappearance; that any method (antiseptics, X-rays) which was capable of killing the bacteria also inhibited the multiplication of the lysin, but if a killed culture was mixed with a living one containing lysin the dead bacteria would be attacked to a certain extent by the lysin together with the living ones (Gratia and Rhodes, 1923); that the concentration of the saline dilution employed, the addition of glycerine, higher or lower temperatures, influenced the rate at which the lysis took place, and thus numerous other factors were most patiently and exhaustively investigated; but the ultimate result can be summed up in a few words to the effect that the characters of Twort's lysin are closely analogous to those of a specific ultramicroscopic virus comparable to the one of mosaic disease in plants, and that to disprove this and prove it an enzyme a most complicated Heath-Robinson-like scaffolding of abstruse hypothesis is required.

Therapeutically applied it has not yet produced incontrovertible results. It sounds very easy to give a typhoid patient a lysin-enema or spray a diphtheria throat with a suitable lysin emulsion; but the effects in clinical medicine are so far in no wise comparable with those obtainable *in vitro*.

Immunization of animals with lysin-dissolved bacteria gives but feeble serums, but there are possibilities that the lysins may be used to deal with the "carrier" problem in typhoid and diphtheria.

The lysin bodies appear to be extremely small, slightly larger than a big albumin molecule, as repeated filtration experiments with compact porcelain candles and colloidal membranes appear to prove. It must however be understood that the smallest trace of bacteriolysin if transplanted into a suitable bacterial culture will very soon multiply in an extraordinary fashion within a few hours. Thus there is always the possibility that a minute flaw in the porous filter or membrane will allow a few bacterial fragments containing the virus to pass through, which then will give rise to Twort's phenomenon, thus inducing a wrong impression of the actual size of the germ; for apparently it can be detected under a good oil-immersion and dark-ground illumination as an extremely minute refractile granule in the body of the bacteria; in addition the eosinophil detritus left by dissolved bacteria is very suggestive. It is evident that a few hundred albumin molecules getting past a flaw in a filter would cause no appreciable difference in a filtrate, and there is no method of detecting such slight flaws or irregularities.

If, however, these objections do not hold good Twort's microplasms must be among the smallest known, though the virus of fowl-pox is capable of passing such close filters that it ought to be even smaller than an albumin molecule.

It is but fair to give the reasons which persuade many investigators to consider Twort's microplasm as a product of the bacterium. As representative one can take R. Otto and H. Munter, who consider an enzyme for the following reasons:—

(i) Because it is possible to cultivate *in vitro* a pure bacteriolysin without the need of isolating each time the corresponding bacterium from man or animal.

Answer: Otto and Munter say that a bacterial lysin can be obtained *in vitro* "wenn auch nicht regelmässig"—it really should be "ganz regelmässig," and even then it is not quite clear what the argument proves, for it is definitely known that Twort's lysin, in common with many other microplasms, can only multiply in suitable living cells. Such is the case with mosaic disease which is mechanically transferable from leaf to leaf of the same plant.

(ii) Because bacteriolysin which has been inactivated through heat when added to living cultures containing lysin will enhance and increase its power. Otto and Munter consider that it is difficult to understand how killed bacteria should favour the generation (Entstehung) of new microbes.

Answer: This observation is not without analogy in bacteriology, and has been previously experimentally confirmed with other microplasms. Much of Gye's recent work is founded on this principle. Levaditi also found that the injection of any microplasm favoured the multiplication of any pre-existing virus.

(iii) Because of the analogical observations of Ehrenberg on albuminoid enzymes, which show that enzymes can be cultivated *in vitro* through many generations.

Answer: These experiments are open to different interpretations and will have to be more solidly supported by independent confirmation before they can be accepted as valid.

For the above three reasons Otto and Munter are of the opinion that the action of the bacteriolytic substance is due to exceedingly small albuminoid particles, which originate from the bacteria themselves under certain circumstances, e.g. age, and that these

particles possess a fermentative action which is liberated by the crumbling (Zerfall) of the bacteria.

This ought to be an accurate translation of their views which are given as an example among many. The views of the writer of this paper are: Twort's lysin is particulate, visible by dark-ground illumination by which means the lysis can be followed in all its details; it can be stained as an extremely minute eosinophil granule; it has the necessary characteristics of a microplasm—rapid specific intracellular multiplication in suitable living bacterial cells; is therefore not a bacterium, spirochæte or protozoon, nor, in view of its rapid multiplication, an enzyme. Every bacteriolytic virus is specific for a certain bacterium, and accordingly there are as many distinguishable bacteriolytic viruses as bacteria subject to this peculiar disintegration.

D'Herelle himself, who holds that all bacterial lysin-bodies are but slight variations of a single virus, has experimentally proved that the affinity or specificity of a lysin-body for a certain bacterium is practically unalterable and will persist after having been propagated in a certain bacterium for years through hundreds if not thousands of transplants. He relates that in 1916 he isolated an active lysin for Shiga's bacillus, which also dissolved *B. coli*, but to a lesser degree (moyennement actif), and only very slightly, *B. typhosus* and *B. paratyphosus*. During 1917 to 1919 it was transplanted about 1,200 times in *B. shigæ*, and yet at the beginning of 1920 it had the same medium virulence for *B. coli* and feeble lytic properties for *B. typhosus* and *B. paratyphosus*.

Following this evident and clinching experience d'Herelle goes on to refer to the experiments of G. Eliava, who, having isolated a lysin from a *Staphylococcus aureus* of an abscess, propagated it over one hundred times with the staphylococcus, mixed 0·25 c.c. with 10 c.c. of Shiga bacillus emulsion, found that immediate culture on agar resulted in an ordinary streak of dysentery bacilli, but after the emulsion had remained in the incubator for twenty-four hours at 37° C. the agar plating grew to a bacterial "spread" with four blank spaces containing Shiga lysin, and successive transplants enhanced this virulence.

From this experiment d'Herelle concludes that the specific properties of lysin body can be varied at will, but in several other parts of his most interesting book, "Le Bacteriophage," several other equally convincing observations are reported contradicting this view.

As a result it is to be feared that the experiments tending to prove that a bacteriolysin can be accustomed or made virulent for all other bacteria suffers from an evident flaw known to those who have worked on the subject, and indeed observed and recognized by Twort in his first paper—that is, the "latent" property of the virus, which will remain cryptic for several generations and then suddenly appear *in vitro* and spread rapidly. And this indeed is a common character of many viruses.

It should be mentioned that d'Herelle otherwise knows that Twort's bacteriolysin is so strictly specific that he considers it could be used as a test for the identification of certain bacteria.

IV.—Virus Diseases of Plants.

Though Pasteur in 1881, whilst discussing the properties of the virus of rabies, intuitively foresaw that it might be invisible with our ordinary microscopic method and therefore filter-passing, the first definite experimental knowledge of a filter-passing micro-organism or virus was due to the study of a disease of the tobacco plant.

Iwanowsky and Polotzoff in 1892 proved that the so-called mosaic disease of the tobacco leaf was due to a germ which was so minute that it passed through a filter which held back ordinary bacteria. These results were independently confirmed in 1898 by Beijerink, who considered that mosaic disease was due to a "contagium vivum fluidum," a living, fluid contagious matter—because it was invisible to ordinary microscopic methods, passed easily through filters, and above all because it diffused through agar-plates. All these arguments are not proof positive, and an extremely minute corpuscle under the range of microscopic visibility will perform all these feats and many more. Beijerink mentions in his paper the existence of peach yellow and peach rosette, plant diseases described by Erwin Smith in 1894, and suggests they are due to filter-passers, and in this he was right, for they have been proven since to be caused by a virus.

Following these pioneer investigations many other plant diseases of a similar type have been described, in the tomato, potato, cucumber, sugar-beet, sugar-cane, maize, clover, orchid, peach, &c., some of which can be easily mechanically transferred, whilst others appear to require an intermediate insect vector, and somewhere the transmission can be only accomplished by autoplasty or graft.

Mosaic disease in tobacco and leaf-roll in the potato appear to be disseminated by green-flies (Aphidæ), though any healthy plant can be infected by dipping a needle into the diseased portion of a leaf and then scratching the leaf of a suitable plant; for it must be kept in mind that these filter-passers (in common with many others observed in animals and man) are strictly specific, that is, will only multiply and cause corresponding pathological symptoms in a certain plant and that one only.

It has indeed been observed with leaf-roll disease of potatoes that a plant of the same family on being grafted with portions of a leaf-roll diseased potato plant will develop no symptoms, but if at any later period a small piece is grafted on a healthy potato stock, it will infect them; in other words, a plant of the same family is capable of acting as a "carrier," a term and condition well known in clinical medicine.

From the standpoint of analogy with certain animal diseases it is interesting to know that the virus of mosaic disease in the tomato can be proven to be present in every part of the plant; even the hairs on the surface of the tomato leaf if snipped off and injected will cause the disease in healthy tomato

plants, but this notwithstanding the mosaic patches appear in the green leaf and there only.

These observations and many others in connection with animal disease show clearly that filter-passers cannot be studied separately and distinctly according to whether they occur as parasites of bacteria, plants, animals or man, but have to be investigated as a whole because, *mutatis mutandis*, they react towards the cells of their host, whether a vegetable or an animal, according to certain generally recognizable, definite rules.

V.—Virus Diseases of Animals.

In 1897, Löffler and Frosch proved that lymph taken from the blisters of foot-and-mouth disease of cattle, when suitably diluted with water, could be filtered and that the filtrate was still definitely infective and could reproduce the disease in cattle, and that this process could be apparently indefinitely continued until such dilutions of the original infecting dose were eventually obtained, as to render extremely improbable that the symptoms were caused by a toxin or any similar fluid. Hence they accepted the existence of extremely minute living organisms as a cause. They also concluded that :—

"Should further investigations confirm that the (pathological) results of the filtrates are due to extremely minute living organisms, as indeed all appearances suggest, then one would feel inclined to believe that the cause of many other diseases of man and animals, such as small-pox, cow-pox, scarlet fever, measles, typhus, rinderpest, which up to now have been unsuccessfully searched for, may be found to belong to this group of smallest among germs."

It can be said that these conclusions show a creditable amount of foresight!

The virus is thus filtrable, invisible with ordinary optic methods, and has so far resisted artificial cultivation.

Nocard and Roux, and Salimbeni in 1898-9 announced the filtration and subsequent artificial cultivation of the germ of peri-pneumonia or pleuro-pneumonia of cattle, a very infectious epizootic disease limited to bovines, characterized by a simultaneous inflammatory condition of the pleuræ and lungs. It is transferred by contact, the virus is not contained in the blood but only in the tissues affected. The germ retains its virulence for nearly a week in artificial cultures on agar, where it forms minute colonies of short, slender, very mobile and polymorphous rods, differing therefore in this particular from many other viruses or microplasms.

This disease and the micro-organism causing it appear to be in a class by themselves, and may prove to be a connecting link between bacterial diseases and those due to cytotrope viruses or microplasms. Borrel considers the agent of peri-pneumonia to be a bacterium and has given it the name of *Asterococcus mycoides*.

Protective inoculations with pure cultures have been successfully practised, though the serum of immunized animals shows but feeble protective properties.

Also in 1898 Sanarelli described a peculiar disease of rabbits at Montevideo, characterized by a catarrhal blepharo-conjunctivitis of the eyes followed by swelling of the nose and mouth, anus and genital regions, and sometimes the appearance of small subcutaneous, gelatinous tumours in various parts of the body. In does the nipples may become hypertrophic

It is true that definite proof of the filtrable properties of this virus was not forthcoming till 1911 when it was shown to be so by A. Moses, of Rio Janeiro, after unsuccessful attempts by A. Splendore in 1909, but, from the first, microscopic appearances were recognized to be those of a cytotrope virus-disease.

In 1900 McFadyean discovered the filtrable properties of the virus of African horse sickness, an acute febrile disease with œdema of the eyes and neck, and terminal pulmonary œdema. Its transmission in nature by a mosquito or stable-fly is suspected but experimentally ingestion of the filtered virus will produce the disease. These results were confirmed by Nocard in 1901, though a somewhat similar disease of bovines, called "barbone," is caused by a non-filtrable "pasteurella," *P. bovi-septica*.

Also in 1901, Centanni and Savonuzzi and a little later Maggiora and Valenti described a disease of blackbirds and also other birds (fowl pest) characterized by pericarditis and intense congestion of the lungs. The virus is filtrable and cannot be artificially cultivated.

In 1902 Nicolle and Adil Bey proved that the virus of cattle plague is a filter-passer.

The disease consists in a sero-purulent inflammation of the mucous membranes, rapid emaciation and bloody diarrhœa. The transmission is by contact and contamination of the food by excreta. The virus is resistant, is still infective after drying for a week or even twelve days, or can be retained on hay kept in the dark for a couple of months or more.

The germ is neither visible nor has it been cultivated.

In the same year Borrel published his results with the virus of clavelée or sheep-pox. This is an acute febrile contagious disease of sheep, consisting in a generalized eruption of papules, vesicles and pustules not very deadly, and leading to complete immunity after recovery. Transmission is by contagion.

The cytotropic virus is filtrable, very resistant to drying and retains its virulence for two years if kept in a dry place.

Marx and Sticker also in 1902 published the filtrable nature of the virus of fowl-diphtheria and fowl-pox which are different localizations of the same germ, as proven by Carnworth, Hutyra and Marek, Borrel and others. These are fairly common diseases well-known to fowl breeders for many decades. Infection is by contact or ingestion of soiled food. The type of disease varies according to localization—it more commonly consists in warty excrescences of the comb, corner of the mouth or eye, folds under the wing, vent, &c.

These epithelial proliferations may break down, yet heavily bacterially infected, coalesce and then do resemble small-pox, but equally often only sma

lumps or tumours are formed which shrink and dry up in the course of a month or so.

One noticeable property of this virus is called "dermo-tropismus" by Lipschütz, and consists in the experimental observation that if one injects a fowl intravenously with the virus no proliferations will appear except at places which have been artificially irritated by scarifying or rubbing with sand paper. This peculiarity it shares with vaccinia and to a certain extent other viruses which will "localize" or produce pathological alterations in positions which have been mechanically injured.

This virus is important from the standpoint of analogy, for it is capable of producing extensive epithelial proliferations and presenting several features which remind one of warts and thus also of epithelioma. It is true that no metastasis results and that the warts disappear spontaneously; and thus Borrel no doubt was justified in saying that the condition is analogous, but by no means identical with cancer.

The virus is extremely virulent, will act in dilutions surpassing one in 100,000, and moreover does not always give rise to epithelial proliferations, for if it happens to attack or multiply in the mucous membranes of the mouth and windpipe a membranous exudation with abundant bacterial invasion will result, the air passages may be obstructed, and death with œdema of the lungs follow. Immunity occurs after recovery.

In 1903 Roux, and soon after Borrel, reviewed the knowledge obtained by the investigation of filter-passing viruses.

Roux includes among them foot-and-mouth disease, peri-pneumonia of cattle, virus myxomatosus of the rabbit, mosaic disease of tobacco, African horse sickness, fowl-plague, yellow fever, sheep-pox and rinderpest.

Borrel's list includes foot-and-mouth disease, sheep-pox, fowl-pox, rinderpest, vaccinia and variola. To-day (1925) the list would embrace over fifty diseases of plants, animals and human beings, and may yet be considerably added to.

Two other animal diseases caused by filter-passers should be considered, owing to the peculiar symptoms they are capable of producing. One of these is infectious agalactia of sheep and goats, whose germ was proven filtrable in 1904 by Celli and Blasi; and the other, swamp fever of horses, an infectious chronic fatal anæmia of horses, the filtrable properties of the germ in the blood and urine being demonstrated by Carre and Vallée in 1904. The disease is peculiar to horses; infection is possible by injection and ingestion of the filtrate, the resulting hæmatological picture showing striking resemblance to some cases of pernicious anæmia in man. Analogous diseases in fowls are also known.

The investigations in connection with hog cholera or swine fever are specially important and interesting. For a long time this disease was considered to be a septicæmia due to a bacterium of the *coli* group—*Bacterium choleræ suum*—which could be isolated from the blood and dejections in a very great percentage of the animals affected by the disease. The serum of a great number was also found to react practically specifically with the bacterium, which as a matter of fact could be recovered from the intestine of a large proportion of healthy pigs.

This notwithstanding that de Schweinitz and Dorset (1903) proved experimentally that the disease was due to an unrecognized filter-passer, and this was further confirmed by Dorset, Bolton and McBryde in 1905. It was then found that a simple infection by the filter-passer gave the appearances of swine-fever, but where a superadded invasion of the system by the *B. choleræ suum* took place then hog cholera resulted.

Immunity is complete after recovery. Protection by injections of serum from immune hogs is very successful. Personally I have seen herds of 200 or more porkers saved by these means, in an outbreak taken in its early stages in a breeding establishment where practically the whole herd had been wiped out by a previous epizootic.

Some forms of distemper in young dogs were shown to be due to filter-passers by Carre in 1905, and Theiler and Robertson proved the same fact in the case of catarrhal fever of sheep—so-called "blue-tongue."

These animal diseases have been mentioned to show the economic importance of filter-passers and it may be said that the number is yearly being added to, by the inclusion of diseases which have long been suspected of being due to viruses and others where this ætiology had never been previously suspected.

Epitheliosis contagiosa in fowls has been previously described and its analogy with cancer alluded to, but with the discovery by Peyton Rous in 1911 of a peculiar fowl-sarcoma which was proven to be due to a filter-passing virus, originally strictly specific for Plymouth Rock, later producing neoplasms in other breeds of fowls, the study of proliferative viruses received a great impetus.

Peyton Rous further described two other neoplasms of the fowl, which could be induced by a cell-free filtrate, an osteo-chondro-sarcoma and a peculiar reticulated sarcoma. In the course of experiments it was found that when dried these sarcomatous tissues could be kept for months and then ground up, suitably emulsified and then give rise to the corresponding neoplasm. In addition he observed that intravenous injections of the virus alone did not give rise to tumours and that it was necessary to inject a small quantity of diatomaceous earth with the virus to induce proliferation in the connective tissue and help the formation of a tumour. Numerous other growths of fowls were investigated and the majority of them were found to belong to one of the three groups mentioned above.

Murphy and Rous found that chicken-sarcoma when implanted into chicken embryos was capable of producing malignant transformation in the mesodermal tissues only—a further proof of its "specific" nature.

It should be noted that spontaneous sarcomatous fowl tumours exist which cannot be transferred by a cell-free filtrate or after desiccation.

Quite lately S. Adler (1925) has described a disease

of fowls in Palestine characterized by leucocyte inclusions, which are of the chlamydozoon type. The disease resembles fowl-spirochætosis, attacks Rhode Island Reds, Leghorns and hybrids of the above varieties with native fowls, but—and this is important—native fowls are not observed to be attacked. The symptoms are fever up to 110° F., diarrhœa with greenish droppings, death within fourteen days. Liver and kidney show fatty infiltration and patches of necrosis, numerous chromatic inclusions in the protoplasm and also nucleus of leucocytes.

Native fowls (three out of twenty-five examined) were observed to show the same inclusions in leucocytes, the inclusions persisting in the blood from one to seven weeks during which time the leucocyte count rose to 34,000.

Therapeutic trials with arsenical preparations were found to be fruitless. Experiments with ticks failed to transfer the disease.

Filtration is not mentioned, but the careful observations recorded enable one even without the winged touch of Sambon's methods in epidemiology to recognize the disease as due to a "virus" though it differs from fowl-leukæmia in many particulars.

VI.—"Virus" Diseases Transmissible from Animals to Man.

So far the diseases reviewed are restricted to animals or plants, and their interest for the clinician possibly remote, but with the experimental proof brought in 1904 by Remlinger and Riffat Bey and later di Vestea that the virus of hydrophobia or rabies could pass a Berkefeld filter and remain infective, a new group of diseases was brought into purview—those common to or rather transmissible from animals to man, for the accidental human contagion with the virus of foot-and-mouth disease is not common.

The symptoms of hydrophobia are well known; therefore it is sufficient to mention that certain peculiar intracellular corpuscles discovered by Negri in 1903 are now considered diagnostic signs of the disease, if found in the brain of suspected dogs or other animals, and that the virus shows a peculiar affinity for the nervous system, though also found in the secretion of the salivary, lacrymal and mammary glands, and occasionally in the blood and inner organs. The germ will retain its virulence if kept in the dark for months, if not years.

Small-pox, Vaccinia, Milk-pox (Amaas), Varicella.

In 1905 Negri and later in 1906 Nicolle and Adil Bey showed that vaccinia—that is the lymph used in vaccination — retains its properties after passing through a Berkefeld filter and the coarser grades of a Chamberland filter. These filtration results have been contradicted by numerous other observers, including Thomson (1924). But there can be no doubt that given suitable technique (dilution and partial discrete maceration) the experiment succeeds, as shown quite lately (1925) again by Mervyn H. Gordon, who states conclusively that "Vaccinia, therefore, is now definitely included among the filtrable viruses."

In 1908 Casagrandi confirmed the filtrability of the virus of smallpox—variola, as might be expected because the two viruses, if not identical, are at least very closely related. The virus of the third disease of this group, variously called milk-pox or mild small pox, varioloid, alastrim, or amaas, is also filtrable (M. H. Gordon). It differs from vaccinia in so far that it fails to "take" in the rabbit or calf, but can be made to do so after repeated passages through monkeys.

Whether these three viruses are identical and their virulence simply slightly altered by passages through various animals is a matter which has been fiercely contested since the days of Jenner and it cannot be said is yet completely decided, because individual opinions as to the meaning of the word "identical" and "different" vary considerably. Jenner has already observed that one could inoculate cow-pox and small-pox at the same time and produce a "mixed" disease, for the principal difference between the two is that vaccinia remains localized and small-pox spreads in man. In Jenner's observation the mixed variola-vaccinia in the course of six months became completely vaccinial, for the small-pox virus had died out.

M. H. Gordon's report (1925) gives full information on these matters, though his investigations are not yet completed.

Varicella or chicken-pox is not only clinically but also experimentally a different disease altogether, its virus is not inoculable to laboratory animals, and in various precipitation tests has been shown by M. H. Gordon to be sharply differentiated from vaccinia and variola.

The group of "pock" disease in man and animals is great and most of them appear transmissible from animals to man by the method of cutaneous scarification. Jenner figures a cutaneous vaccination in a child with pus from the heel of a man suffering from horse-pox (I believe also called heel-grease—*germane* Pferde-Mauke); and diseases of the same group are known in the sheep-dog, goat and also birds, and though their naked-eye appearance is very similar the viruses are distinguished by experiment and cross immunization by inoculation.

Before concluding it may not be without interest to call attention to the fact that the cerebral localization of vaccinia has been clinically noted in very rare cases, the symptoms resembling tetanus.

Trachoma is a widely spread infective, chronic human conjunctival disease which soon renders the palpebral conjunctiva thick and velvet-like. It also spreads to the cornea and often, even if cured, leaves behind scars and opacities. In certain chronic conditions it is extremely difficult to differentiate from other similar ophthalmias.

Bertarelli and Cecchetto in 1907 inoculated a macacque monkey with the filtrate from the granulations of another monkey which had been previously infected with human trachoma virus and thus reproduced the disease in series.

Trachoma bodies or Prowazek-Halberstädter bodies are small chlamydozoic structures and a constant

feature of early cases. Later invading bacteria render the search and recognition very difficult.

The researches undertaken on these various animal and human diseases prove that filter-passers are selective in their pathological action on the animal body; that is they show a definite tendency to attack certain groups of cells, and cause in the beginning alteration in those cells and those only. Later bacteria join in the fray and conditions can with difficulty be distinguished from generalized bacterial invasions—witness the experience with hog-cholera and swine-fever and various forms of dog distemper.

VII.—Neurotrope Viruses.

We now come to a group of human and also animal diseases caused by filter-passing viruses which have not yet been experimentally clearly differentiated and classified. The diseases they cause are clinically fairly distinct; pathologically the common tendency is to attack the central nervous system and cause certain definite alteration, especially in the nerve cells and around capillaries.

Rabies has certain affinities to the group and to a lesser extent also the virus of mumps; though the latter may be due to a minute spirochæte. Rabies, however, does not cause the histological alterations in the central nervous system which have been shown to occur as the result of infection with a true neurotrope virus, and in addition has already been considered under diseases transmissible from animals to man.

In animals there is a big group of diseases of the central nervous system which appear epizootically, are evidently infectious, and result in paralysis and rapid muscular atrophy; examples are Borna's disease in horses, Aujeszky's disease in cattle and similar spontaneous infections of goats, rabbits, guinea-pigs (Jonescu-Mihaiesti), though some which to all outward appearances should belong to this group, are either due to protozoa or obscure causes.

Poliomyelitis.

The first human disease of this group to be clinically recognized and studied was poliomyelitis, the well-known acute febrile disease of children and young adults, which results in a more or less extensive paralysis and rapid atrophy of muscles, especially of the lower limbs.

Pathologically, the lesions of the brain and spinal cord consist in perivascular round-celled infiltration (cellular cuffs), small hæmorrhagic foci in the grey substance, meningeal inflammatory processes, leucocytic groupings and above all cytolysis of the big motor cells of the anterior horns of the spinal cord, which in chronic cases progresses to a condition called "neuronophagia" by Levaditi.

The virus of poliomyelitis proved eventually to be filtrable and transmissible to monkeys, but before this conclusive result was obtained, numerous bacteria and in some cases even protozoon-like micro-organisms were isolated and published so that in some instances investigators came to the conclusion that infantile paralysis could not be a pathological entity, but was due to a variety of causes. In fact Hoche in 1890 had considered he could produce the cerebral lesions of poliomyelitis by the injection of inert substances and bacteria into the veins of rabbits. This result is due to the common confusion of "general resemblance" with "major signs." Later, in 1908 Allen Starr and Martha Wollstein examined cerebro-spinal fluids of twenty cases of poliomyelitis and definitely stated that artificial cultures on various media aerobically and anaerobically remained absolutely sterile.

In 1909 Landsteiner and Popper succeeded in transmitting the virus of poliomyelitis to two monkeys, which became paralysed six and seventeen days after the inoculation of minced and emulsified spinal chord from a typical case of poliomyelitis in a child of 9 years. Rabbits, guinea-pigs and mice were unsuccessfully injected in the same time. Transmission of the virus from the two monkeys also failed.

Similar results were obtained by Knöpfelmacher in 1909, but in the same year practically simultaneously Flexner and Lewis in New York, Leiner and Wiesner in Vienna, Landsteiner and Levaditi in Paris, succeeded in transmitting the virus to a monkey and from this one to others in series. The inoculation of the human virus to rabbits, guinea-pigs and many other animals has so far failed or given uncertain or frankly fallacious results.

The filtrability of the virus of poliomyelitis was also practically simultaneously discovered in Vienna, Paris and New York, by Leiner and Wiesner, Levaditi and Landsteiner, Flexner and Lewis. The incubation of the disease in monkeys injected with a filtrate is longer than when an emulsion of nervous tissues is used—this may show that the virus is retained to a great extent by the filter.

Levaditi has artificially cultivated the virus together with monkey nerve-cells and produced poliomyelitis in monkeys with the fifth transplant of such virus, which will remain virulent for three weeks.

Pieces of medulla placed in 50 per cent. glycerine will retain their virulence for 202 days at least according to Landsteiner, Levaditi and Pastia—and according to Flexner and Amoss as long as six years!

Heat at 50° C. during one hour will kill it, but temperatures below freezing are supported for a considerable time. Virus kept for twenty-five days in milk was attenuated but not destroyed.

Pieces of spinal cord will resist drying over potash at 22° C. for twenty-four days; if the drying is done in vacuum over sulphuric acid pathogenicity will be retained for a fortnight at least.

Antiseptics destroy the virus in the usual surgical solutions and strength, though thymol 1 per cent. and carbolic 0·5 per cent. show but slight action. The simplest and most effective *in vitro* disinfectant for the virus of poliomyelitis appears to be a 1 in a 1,000 solution of permanganate of potash, which is also very effective in relation to the virus of vaccinia (Mervyn Gordon, 1925).

The practical application of these experimental observations lies in the established fact that the virus

may be present for a considerable time in the naso-pharyngeal cavity of children who have suffered from the disease, not only that but " carriers " may harbour the virus in their naso-pharynx without developing clinical symptoms and thus infect others ; in addition infection takes place through the oral cavity and nose, and thus a simple and non-toxic mouth-wash is indicated.

Levaditi and Landsteiner have observed the gradual loss of virulence in the course of numerous serial passages through monkeys. This is not an uncommon experience when dealing with filtrable viruses, in general, and to my mind explains the dying out of epidemics of poliomyelitis and encephalitis.

Diffusion of the disease takes place through contact or the intermediary of soiled objects; the common *Stomoxys* mechanically disseminates the virus and has been proved to do so experimentally. It is still doubtful whether it does so in nature. Epidemics usually develop in summer and early autumn, and subside during the winter.

In view of the well-known resistance of filtrable viruses to drying, dust must be viewed with evident suspicion, and indeed Neustadter and Thro induced poliomyelitis in a monkey by injecting it with 50 grm. of dust from the room of a patient with poliomyelitis. Stable flies, bugs, lice, fleas, have also been investigated as possible carriers of the disease, but with the exception of stable flies results have been negative. We have, however, seen that contact and the existence of carriers are quite sufficient to explain the spread of an epidemic of poliomyelitis, though admittedly most striking exceptions have been noted, where diseased children have been in contact with over fifty others, and no other case has developed.

The virus is therefore as selective in the individual it attacks as it is in the selection of the cells it invades.

Flexner and Noguchi have succeeded in artificially cultivating minute " globoid bodies," which are just visible under the microscope in the shape of short chains or clumps, which can be stained by eosin-azur. In this the virus differed from many other filter-passers, for so far they have not yielded cultures *in vitro*.

Filtrable Herpetic Virus.

Here we approach a very big group of viruses, which may eventually prove to be one single virus with numerous degrees of virulence or several slightly different filter-passers.

In 1913 Gruter, by infecting the cornea of a rabbit with material from a corneal ulcer of a man, produced the same pathological alterations, namely phlyctenular kerato-conjunctivitis.

These results were confirmed in 1919 by Löwenstein, who showed that the virus from all herpetic lesions is pathogenic for the cornea of rabbits with the exception of herpes zoster or shingles. Numerous other observers found these observations correct, but Luger and Lauda in 1921 proved that the virus of herpes was filtrable, though the filtrate is less active than the original material.

Blanc and Caminopetros (1921) showed that genital herpes in man is produced by a virus which is invisible, non-cultivable and filter-passing, which at times is capable of localizing itself in the brain of experimentally infected rabbits and causing encephalitic symptoms and signs, though the cornea only was originally infected. In other words, though the virus in man causes visible pathological lesions of the epithelium, in the rabbit the same virus shows definite neurotropic tendencies. Luger, Lauda and Silberstein (1921) investigated numerous filtrates from herpetic vesicles which developed in the course of numerous feverish conditions such as pneumonia, chronic lung tuberculosis, endocarditis, meningitis, middle-ear disease, &c., and found they were all pathogenic for the cornea of the rabbit. Corneal inoculations with control material from other sources gave no result.

Guinea-pigs were found to be equally suitable for experiment. The virus was found to be active in dilutions of one in a thousand, but varies very considerably in its virulence. In the course of transmission from rabbit to rabbit it may increase. Some attack the cornea alone, others will readily spread to the central nervous system; as a rule in the animals infected it can be detected in the blood, the spleen and central nervous system.

Cases have been observed where herpes was present on the lips, but no virus could be detected in the saliva, and vice versa saliva of apparently healthy persons was found to contain the virus.

Ravant and Rabeau inoculated the cornea and brain of rabbits with cerebro-spinal fluid from cases of herpes with a positive result.

The outcome of all these researches is that in numerous instances one can detect a filtrable virus whose presence makes itself remarkable only in the course of an infection caused by some definitely known bacterium; its relation to the virus of epidemic encephalitis is discussed later on.

Encephalitis Epidemica Lethargica.

This disease had apparently been observed in Italy in the fourteenth century, later at Tübingen in 1712, and again in Italy, Austria and Switzerland about 1890. It is very probable that single sporadic cases have existed in Europe ever since, but the first complete, exhaustive clinical study was published by von Economo in the course of a small outbreak in Vienna in 1917. In England it was recognized early in 1918, and since then the dread disease has spread over a good portion of the inhabitated globe. The symptoms of the disease can be divided into acute, chronic and after-effects or sequelæ. Its infectivity is low, but of long duration—outbreaks in institutions have been described, physicians and nurses have contracted the disease from their patients, mothers have been known to infect their babies, in fact several cases have occurred in a household.

The sequelæ, after-effects or residues are most important, as they occur in one form or another sooner or later in proportions varying between 50 to 75 per cent., according to different authors. These

ate manifestations consist in the Parkinsonian syndrome in some and a profound alteration in character amounting to evident mental disease in many others.[1]

The search for the causal agent proved difficult and is still being continued, because numerous similar viruses appear to exist in man and animals, which though they give rise to clinically distinct symptoms in the course of a natural or epidemic infection, when injected into rabbits or monkeys in various fashions may be followed fairly constantly by a diffuse encephalitis, microscopically very similar to the human disease. Not only does the virus of human encephalitis belong to this group, but also that of febrile herpes, and another studied by Bull, Oliver, Wright and Craighead and found to be a filter-passing germ about one-fifth of a micromillimetre in size which produces both naturally and experimentally a mortal encephalitis in rabbits.

Moreover, C. C. Twort and Archer described a diffuse encephalitic condition in the rabbit which Levaditi eventually considered to be due to a minute sporozoon called *Encephalitozoon cuniculi*.

All these pitfalls and disturbing factors have only extended the number of researches and confirmatory experiments, but cannot invalidate the main results, any more than the ubiquity of spirochætes has stayed the triumphal march of discoveries and clinical applications which followed the detection of the *Treponema pallidum*.

It may however be mentioned that Wiesner in 1917 originally isolated a diplo-streptococcus, Löwenthal and also Manteufel reported the finding of influenza bacilli, whilst Rosenow and Jackson found cocci in short chains in every one of twenty-one cases. James and McIntosh (1918) recorded negative cultural results from eight fatal cases. These short notes prove some of the difficulties of experimental research in this branch of medicine; there are many others.

Early in 1919 Strauss, Hirschfeld and Loewe (New York) published the results of experiments with a *Macacus rhesus* which had been inoculated intradurally with brain emulsions from a case of epidemic encephalitis, and, later, on rabbits injected with the naso-pharyngeal washings from patients with the same disease. The results were positive with the monkey, that is, the animal thus infected died in a few days with a diffuse analogical encephalitis which could not be transmitted.

The lesions in the rabbits were not very conclusive, and we now know as the result of the extensive investigations of Levaditi and his many collaborators that rabbits do not get easily experimentally infected with human virus, but that after passage through a monkey the virus may assume pathogenic properties for rabbits.

In 1920 Levaditi and Harvier by crushing and grinding up the brain substance of a woman who had died of encephalitis lethargica and who in addition presented symptoms of herpetic disease (herpes febrilis), produced by intradural injection a condition of encephalitis in a rabbit which ended in death. By transmitting this encephalitis in series through other rabbits they succeeded in obtaining a virus which passed a Chamberland candle and whether inoculated into cornea, skin, intravenously or intracerebrally, gave rise in each case to keratitis and eventually encephalitis

These results are complicated by the disturbing factors already suggested, but the experiments of Levaditi and his numerous collaborators have now been repeated so often and in so many different fashions, and also confirmed by many other investigators, that it is impossible to uphold many objections which have been raised in the past.

In 1919 McIntosh and Turnbull injected emulsified brain substance from a case deceased at Derby into the brain and peritoneal cavity of *Macacus rhesus*. In addition part of the emulsion was passed through a Berkefeld filter and injected in the same fashion into a *Cercopithecus patas*, who died two months afterwards with hæmorrhagic lesions and diffuse encephalitic symptoms.

Netter, Cezari, Durand (1921) inoculated the filtered brain emulsion and also salivary glands from a fatal encephalitis case which had lasted fifteen months and obtained a positive result.

Kling (1922) confirmed this result with the cerebrospinal fluid of a case of post-encephalitic paralysis agitans over eighteen months after the acute onset of the disease. Sicard, Paraf, Laplane (1923) injected a rabbit with mesencephalic emulsion from a case of post-encephalitic Parkinson's syndrome which ended fatally four years after the acute onset of the original symptoms, and even then obtained a positive result.

These observations are extremely important, for they prove how long these filtrable viruses can persist in the system, and, we surmise, remain virulent and transmissible to new victims given suitable circumstances.

Encephalitis lethargica being thus due to a selective filtrable virus, it was to be expected that in common with rabies and Borna's horse encephalitis it should give rise to a typical cellular reaction of a chlamydozoic nature.

In 1919 Da Fano and Ingleby described minute granules in the protoplasm of nerve cells; later Da Fano detected them intra- and also extra-cellularly. In 1923 he produced meningo-encephalitis in the rabbit with virus from herpes febrilis and found in the brains of the animals similar corpuscles. Luger and Lauda in 1921 described similar bodies in spontaneous human herpes febrilis.

Hume, Nattras and Shawe (1921-2) detected Da Fano's corpuscles in four fatal cases, and later (1922) Levaditi, Harvier and Nicolau described "encephalitic neuro-corpuscles," which they detected in 13 per cent. of the brains of animals experimentally infected with encephalitic virus.

In 1920 Loewe and Strauss reported that they had isolated on Noguchi's medium a minute germ, from

[1] I should like to acknowledge my indebtedness to the book on epidemic encephalitis by Arthur J. Hall (1924) for much valuable information on the clinical aspects of the disease.

the brain, naso-pharynx and its washings, spinal fluid and blood of fatal cases of encephalitis. The filtrable artificial culture reproduced the disease in rabbits and monkeys, could be recovered in pure artificial culture from their brains, be re-inoculated in series and preserved its virulence for several months in 50 per cent. glycerine. This is a striking discovery, because we have seen that multiplication of virus does not usually take place outside a living cell.

Levaditi (1922) has shown that among laboratory animals the one most easily infected is the mouse, which can contract the disease whether inoculated intradurally, intraperitoneally or under the skin. The white rat, sheep and fowls appear to resist the infection, and the rabbit and guinea-pig are not always easily infected with human virus.

Levaditi, Harvier and Nicolau (1922) showed that small pieces of brain of rabbits can be dried for forty-four days over phosphorus pentoxide, be pulverized and yet remain virulent. Brain substance can also be emulsified to a dilution of one part in a thousand and yet remain virulent. Heated for one hour at 55° C. it is destroyed. Bile which has but slight influence on the virus of poliomyelitis will inhibit its pathogenic qualities. Among antiseptics permanganate of potash (one in a thousand) has a definite disinfectant action.

The virus can be kept active for ninety-six days in milk at room temperature and for a fortnight in water and will remain virulent for forty-eight hours after death.

Levaditi after numerous cross-experiments on rabbits came to the conclusion that epidemic lethargic encephalitis is due to a specific filtrable virus which, however, exists in four degrees of virulence:—

(*a*) Attenuated in the saliva of healthy subjects where it appears to be fixed to the epithelial cells of the mouth.

(*b*) A slightly virulent form in the blebs of herpes.

(*c*) Very virulent form in the saliva of healthy "carriers."

(*d*) Similar virulent form in the central nervous system of encephalitic patients.

He thus considers the virus of herpes, which is widely spread, identical with that of epidemic encephalitis, and differing from it only in degree of virulence and specific attraction for the nervous system.

Spinal Amyotrophy.

This is a familiarly occurring disease of a definite hereditary character, which many of us, obsessed as we are by the idea of what a bacterium is, can, and cannot do, could never admit as being possibly due to a "germ." It must be cellular metabolism, dysgenic factors, original sin or nothing.

Therefore Levaditi, Landsteiner, Pratch and Zatelli themselves view with a certain measure of philosophic doubt the striking result they obtained in two monkeys which in 1911 they inoculated with an emulsion of the spinal cord of a child suffering from the disease, but who had died of pneumonia. After an incubation of a month the monkeys fell ill and died. Microscopically the spinal cord showed perivascular cuffs, small focal inflammatory reactions in the grey matte and advanced cytolysis in the motor cells.

This observation may be correct or vitiated by som intervening factor such as the ubiquitous herpet virus; but this can be definitely stated—filtrab viruses have a pathology of their own, and in th vertebrate body behave in a peculiar fashion of the own for which an analogy cannot always be foun at least in bacterial bionomics. The spirochæte syphilis does approach filter-passers in its chronicit prolonged latent periods, and selective, if at time erratic, localizations. It differs in its protean manifest ations (examples—condyloma, gummas, aneurysm tabes, general paralysis), for filtrable viruses are fairl constant to type, and above all fairly consistentl selective in the tissues they invade; which thus lead up to the thought that not only they are cellularl selective, but consequently pick out certain individual or families or races.

The subject possesses considerable clinical import ance, for transference through the placenta is possibl for filtrable neurotropic viruses.

It is known and admitted that encephalitis letha gica leads to symptoms simulating Parkinson's disea or paralysis agitans, also that it may cause alter tions in the moral character amounting to ment affliction. It is not too far-fetched therefore t suggest that some forms of idiocy, epilepsy an dementia præcox may yet be found to be residues o after-effects of viruses similar to the ones we hav reviewed.

VIII.—Influenzal Catarrh and Filter-passers.

In 1918 Nicolle and Le Bailly, later Selter and M. H. Gordon, detected in the nasal secretions o patients suffering from influenzal catarrh a filtrat capable of reproducing the disease in human beings These results have been confirmed by several Japanes scientists—Yamamcuchi, Hivashina, Sokokami; bu later, in 1922, Olitzsky and Gates succeeded in cul tivating on Noguchi's medium a small body whic they called *Bacterium pneumosintes*, whose size i just above the limits of ordinary microscopical visi bility—a tenth of the thousandth part of a millimetre

Pure cultures produce in the rabbit pathologica appearances consisting in œdema, emphysema, capil lary hæmorrhages, symptoms evidently occurring in human influenza, a disease, however, in which super added massive infections with *B. pfeifferi* and in other cases various diplococci and streptococci play a great part.

In any case *B. pneumosintes* is visible, cultivable and shows no definite predilection for any type o cell, and produces no peculiar reactive bodies (Chlamy dozoa). It may yet have to be grouped separately from other filter-passing viruses and perhaps be foun to be akin to the germ of peri-pneumonia in cattle.

Thus W. L. Holman and F. H. Knock have bu lately described a minute anaerobe which passe through Mandler, Berkefeld N. and W. filters, whic they recovered from the mouth cavity of thirteen

people, three rabbits and a guinea-pig. It is a definite bacterium and they consider it very similar to if not identical with *B. pneumosintes*.

On the other hand there is an analogy with hog-cholera and swine-fever, owing to the pullulation of definite bacteria which play a conclusive part in the symptoms and also prognosis of the disease.

IX.—Molluscum Contagiosum and Warts (Verrucæ).

For many years the communicability of molluscum contagiosum had been clinically known and carefully observed, but the first experimental transmission in the human subject by means of a filtrate was published by M. Juliusberg in 1906, who filtered the suitably diluted juice from the molluscum of a woman and, having passed it through a Chamberland filter, rubbed the filtrate into his own forearm and that of two other colleagues after slight abrasion of the skin with sandpaper. In one case fifty days after the inoculation about sixty definite mollusca appeared, which on microscopical examination showed the well-known molluscum bodies. In 1907 Serra repeated and confirmed these experiments.

Ordinary warts, the variety which are well known on the hands of schoolboys and schoolgirls, are due to a filter-passing virus. Their contagious nature has been suspected for centuries, and Payne in 1891, Gemy in 1891, Barthelemy in 1896, &c., have published cases clinically proving the transmission of warts from one individual to another, whilst on the other hand, world-famous dermatologists like Hebra in 1866 and Kaposi at the end of last century have considered such reports as old wives' tales. Variot, however, in 1894 inoculated warts from a child to an adult, and Jadassohn in 1895 demonstrated at a dermatology congress warts he had experimentally grafted on his own hand and that of his assistant.

G. Ciuffo, however, in 1907, using the filtrate obtained from warts of the hand of a young workman, inoculated his own hand and noted the development of typical flat warts at the end of five months.

A. Serra has lately carried out a series of experiments with the filtrates of papilliform vegetations from the preputial fold of a peasant 19 years of age and obtained a positive result on his own hand and on the hand of the patient from whom the virus was obtained, but instead of condylomatous growths he obtained simple warts after an incubation of about five months which took about two other months to attain full size. Animal experiments on rabbits, guinea-pigs and dogs were unsuccessful. It is however known that foxhounds develop warts on the mucosa of the mouth, and these are easily transmitted by filtrates (Findlay 1925).

Only a few weeks ago (November 1925) Dr. G. M. Findlay, of the Imperial Cancer Research Laboratories, demonstrated at a meeting of the Royal Society of Medicine warts he had produced on his hand by inoculating a Berkefeld filtrate of the venereal warts from the penis of a waiter from Soho. The incubation was prolonged over sixty days, and the type of wart produced did not correspond to that of the original one, which was papular.

At the time it was mentioned that Dr. A. J. Murray had also been inoculated at the same time but with no visible result.

These experiments are mentioned in view of their importance and possible bearing on the question of cancer ætiology, even if they are only applicable by way of analogy, but the long period of incubation and varying susceptibility of different individuals should be noted.

Some epithelioid warts are histologically true epitheliomata in so far that they consist of epithelial elements only with a slight scaffolding of fibrous elements. They differ of course from malignant epithelioma or cancer by their discrete growth, lack of metastatic deposits and absence of infiltrative diffusion.

X.—Virus Diseases Conveyed by Arthropods.

Leptospirosis.

First among these yellow fever requires consideration, for at one time it was a death-dealing, widely spread human disease (Yellow Jack), whose inclusion among filter-passers is justified by the fact that the virus does pass a Berkefeld, though in reality it is a *Leptospira*, an extremely delicate and minute spirillum similar to the one found free-living in water (Hindle 1925).

In 1902 a commission of U.S.A. doctors (Reed, Carrol, Agramonte, Lazear) studied yellow fever in Cuba and infected human volunteers with a filtrate of the blood of patients taken between the first and third days. Three other Commissions—two U.S.A. and one French—could only confirm these results, but failed to detect the spirillum, though Schaudinn before his death in 1906 had foreseen its existence and discovery, which indeed was accomplished by Noguchi in 1917.

We now know that the mosquito *Ædes argenteus* (*Stegomyia fasciata*) in sucking the blood of the patient also absorbs the *Leptospira icteroides*, which then apparently passes through a stage during which it is invisible or breaks up into minute granules (A. Balfour); after twelve days the mosquito is infective. The *Leptospira icteroides* is a filter-passer in so far as it goes through Chamberland and Berkefeld filters, but the clinical type of the disease is that of other leptospirosis-like ictero-hæmorrhagic diseases, autumn fever (due to *Leptospira hebdomadis*) and infections of a similar nature. The germ itself is not so resistant as the virus of chlamydozoic microplasms, as it is killed by exposure to air at a temperature of 24° to 30° C. in forty-eight hours, and does not survive drying.

Dengue is a febrile disease of tropical and subtropical countries, characterized by severe pains of joints and back, a short partial recovery and then relapse, which after a couple of days terminates the illness. The mortality is low. That it is due to a filtrable virus was discovered by Ashburn and Craig (1907).

Sand-fly fever or three-day fever is a similar benign fever of three days' duration, transmitted usually by

Phlebotomus papatasii or similar sand-flies. The blood on the first day is infective and the virus was discovered to be filtrable by Doerr (1908).

Epidemic parotitis is a clinically well-known disease, and Granata in 1908 obtained from the saliva of children suffering from mumps a filter-passing virus which when inoculated into the blood, parotid gland and subcutaneous tissue resulted in a rise of temperature and a swelling of the parotid gland of one or two weeks' duration. Mervyn Gordon in 1914 then used also a filtrate of the saliva for the intracerebral inoculation of monkeys. Four of the animals died with meningeal symptoms within four days. One monkey inoculated intraperitoneally and intravenously became ill on the eleventh day with swelling of the parotid gland, but no nervous symptoms. Attempts to transmit the virus in series failed.

M. Wollstein (1916) repeated the experiments with cats into whose parotid gland and testicles she injected a filtrate of the saliva of children in the active stage of mumps. After an incubation of five to eight days the inoculated glands became swollen and tender, these symptoms persisting several days.

M. Wollstein in 1918 made further experiments on cats with salivary fluids taken from adult cases in a parotitis epidemic in the military camps near New York City, and found that the virus was a filter-passer, and detected most readily in the saliva during the first three days of the disease, less easily on the sixth day and not at all on the ninth day. It was also detected in the blood of patients showing marked constitutional symptoms and in the saliva of a case of recurrent mumps at the periods of enlargement of the parotid glands, but not two weeks after the swellings had subsided. It was not detected in the cerebro-spinal fluid. She carried out experiments in series and examined histologically the parotid glands and testes of the cats inoculated, finding alterations corresponding to those described in mumps.

Recent researches of Y. Kermorgant have resulted in the detection of a spirillar micro-organism in this disease, but these observations are yet too recent for confirmation, though orchitis and parotitis in monkeys were produced by inoculations with the culture of this spirochæte.

The spirochætal diseases of man and animals of the relapsing fever type, due to a spirillar micro-organism which under circumstances will go through certain coarse-grained filters, need only a passing reference to the variety of arthropods which convey the diseases, including as they do lice and various ticks.

No account of leptospirosis would be complete without a mention of rat-bite fever, which is due to *Spirillum minus* (*Spirochæta morsus-muris*) and also to the peculiar epidemic icterus due to infection with a similar leptospiral micro-organism—no doubt closely allied to the one found free-living in water and fairly easily cultivable in a mixture of fæces and water.

A small outbreak I had occasion to observe in two children of a family, and a young lady aged 24 who lived in the house where the icteric disease was contracted, to my mind was connected with contamination of the food through mice, which had penetrated the fly-proof larder through a small hole in the netting. Mice harbour spironema in their fæces and also blood, and at one time Gaylord, having found the spirillar bodies in cancerous mice, thought the organisms might be the cause of cancer

From an epidemiological standpoint it will be noted that the spirochæte genus is disseminated, transferred or multiplies in several different fashions, which can be summarized as follows:—

(1) Contact (syphilis); (2) diptera (yellow fever); (3) lice (Russian relapsing fever); (4) ticks (African relapsing fever, also fowl spirochætosis); (5) rodent's bite (rat-bite fever); (6) contamination (leptospirosis); (7) innocuous parasitism or infestation (*Spirochæta dentium*)—and in addition are found free-living in water.

In addition their pathogenic properties are comparable in many ways with those of ultramicroscopic viruses in their—(1) filterability; (2) difficult artificial cultivation and isolation; (3) long period of latency in certain diseases (syphilis); (4) transmitted by animal bite like rabies; (5) hyperplastic action on certain definite tissues; (6) individual pathogenicity—syphilis, relapsing fevers, yellow fever; (7) bacterial relationship.

For these and several similar reasons it has often been suggested that all filtrable viruses consist of extremely minute and delicate spirochætes beyond the range of visibility.

Typhus Group of Diseases (*Rickettsia*).

The inclusion of the typhus group of diseases among those caused by filtrable viruses is perhaps artificial. Early experiments showing that the virus of the disease would pass a filter are not of a conclusive nature, but Nicolle in 1920 stated that he considered typhus to be due to an ultramicroscopic virus, though he admits that so far the opinion lacks definite experimental confirmation; he explains, however, that he considers the virus to be so firmly intracellularly situated that it cannot be detached from the protoplasm and so pass a filter. In support of this view he reports the following observation: On centrifuging virulent blood it will separate as usual into three layers—the lowest consisting of erythrocytes with a milky coating or film consisting of white blood-corpuscles and then serum. If the erythrocytes are injected into a monkey they are found devoid of all virulence; the serum under the same circumstances may or may not be active, but in every case the leucocytes are highly virulent—one cubic millimetre being sufficient to cause evident pathological symptoms, whilst a dose of erythrocytes 2,500 times larger will have no effect.

Nicolle also admits that the objection might be raised that bacteria circulating in the blood would naturally tend to collect among the leucocytes; so they would, but hardly in such a strikingly selective fashion.

A disease which has several points of resemblance with typhus fever is trench or Wolhynian fever, which Strong (1918) considers to be due to a filtrable virus, and this disease in common with others of the typhus group has an arthropod as intermediary—the ordinary louse.

The typhus group, though not comprising many human diseases, is widely spread, and the insect vector is not in all cases the same, but varies in different continents. Typhus has been known for centuries in Europe, and is still endemically present in Russia and Poland, in addition to North Africa.

In this instance the virus appears to be conveyed by the common louse *Pediculus humanus*, in its varieties *capitis* and *vestimentorum*. This also applies to tabardillo in Mexico—the local name for typhus. A similar fever described by Megaw in 1921 as occurring on the lower folds of the Himalayas is also disseminated by lice. Rocky Mountain fever, also called black fever or blue disease, from certain districts of Montana and Idaho, U.S.A., is apparently transmitted by a tick, *Dermacentor venustus*. Japanese river fever, kedani mite disease, which occurs in Formosa, Korea and in the Nippon Island of the Japanese Empire, is due to the kedani mite, the larva of *Trombicula akamushi*, similar to our harvest-bug, *Leptus autumnalis*.

All these human diseases are connected with the appearance both in the capillary endothelium of the persons affected by the disease and in the gut of the arthropods conveying the virus of minute peculiar bipolar bodies which so far it has been impossible to classify either among bacteria or protozoa. Rocha-Lima of Hamburg, who fully investigated and described them in 1916, proposed the name Rickettsia, after H. T. Ricketts, who first discovered very similar bodies in the blood of patients and fæces of lice in the course of investigations he was carrying out in Mexico City, where he contracted tabardillo and died.

It is worthy of note that Ricketts saw the bodies in blood, where they are very scanty, and considered them difficult to find in lice, where on the contrary they are usually present in enormous numbers.

Rickettsia prowazeki, which is considered by Wolbach (1922) to be the causal agent of typhus, shows a conclusive, selective predilection for the vascular endothelium cells of infected persons. In infected lice, that is lice which have been fed on typhus patients, it is found usually in massive numbers, filling the protoplasm of the cells of the alimentary tract. They may multiply to the extent of causing the cell to burst, and thus get extruded into the lumen, but their typical position is within a cell.

It must be explained that about twenty different rickettsias have been described occurring in arthropods (insects, Arachnida and Acarina), the majority of them appearing to be harmless parasites of their invertebrate host.

Nöller (1917) discovered a *Rickettsia* in the "ked" of sheep (*Melophagus equinus*). This one has apparently been artificially cultivated on glucose blood-agar medium, but all others have so far resisted artificial isolation.

The position of *Rickettsia* is still uncertain, though on the whole the tendency is to consider them bacterial in nature—in this they resemble certain spirochætes.

Arkwright, Atkins and Bacot (1921) have described bacillary and filamentous forms as part of the developmental cycle of a *Rickettsia*-like parasite of the bed-bug.

Lice also harbour what appear to be a harmless parasite of the *Rickettsia* type, which is distinguishable by its constant extracellular situation in the lumen of the gut, where it multiplies. This is considered a separate variety—*R. pediculi*.

Trench fever has also been considered to be a rickettsiasis, and a laboratory infection appears to confirm this view.

A. Bacot in 1920 contracted trench fever in Warsaw, and thereupon lice fed on his body showed very numerous extracellular rickettsias within three weeks of his developing the fever; this though the same lice for two years had been known to be free from rickettsias. A. Bacot continued to infect clean stock lice fed on his person long after his recovery, in fact three months after the disappearance of all symptoms, four months after his initial attack.

The acceptance of *Rickettsia* as the causal organism of typhus and trench fever makes an explanation of the filtration experiments difficult without further knowledge of its bionomics. Animal rickettsiases are not unknown—Nuttall produced paralysis in a goat by the bites of a tick infected with *Rickettsia*, and Cowdry lately discovered that heart water in sheep in South Africa was due to endothelially situated rickettsia, transmitted by the "bonte" tick *Amblyomma hebraeum*.

XI.—Neoplasms, Parasites and Viruses.

The scepticism of all branches of the medical profession with regard to the existence of a parasitic cause of cancer can be summed up in the words: If cancer were due to a parasite it would have been detected long ago, and in addition we should have cancer epidemics.

Arguments on these lines are sterile. Has the bitter strife about the parasite of malaria been forgotten, the pseudoscientific proofs backed by famous names, which showed it to be an artefact or a ubiquitous micro-organism which could be found in water and mud, the clinching evidence of places with mosquitoes and no malaria and in the alternative of malaria with no mosquitoes?

When Schaudinn first announced and demonstrated his discovery of the *Spirochæta pallida* as the micro-organism of syphilis at a meeting in Berlin, someone, who shall be nameless, got up and said, most urbanely but firmly and with authority, that he had seen and heard in the course of twenty-five years exactly twenty-five different parasites accused of being the cause of syphilis, and then watched them fade away into a deserved oblivion, He knew the same would happen to the twenty-sixth. Has it, though?

If cancer is due to a virus or microplasm, further experimental proof will be forthcoming sooner or later, but it must be understood that great, really great clinical observers were not adverse to entertaining this view of the parasitic nature of cancer.

Sir James Paget, with the polished diction we may well envy and strive to imitate, expressed these views

in a lecture "On Cancer and Cancerous Diseases" in 1887:—

"I believe that micro-parasites, or substances produced by them, will some day be found in essential relation with cancers and cancerous diseases. Mr. Ballance and Mr. Shattock have indeed lately failed to find any; and if, in such a question as this, negative evidence could prove a negative, certainly theirs might make us hopeless. I would not be so, especially if workers so earnest and so skilful as they are will continue the search."

That cancer usually develops in individuals over forty is a disconcerting factor, and many other observations which at present appear inexplicable from a parasitological standpoint have been made; but pathology has presented and still presents many similar riddles which even in my time have been solved or are being partially and gradually explained. Let us call to mind general paralysis of the insane—we now definitely know that it is a late syphilitic manifestation with spirochætes in the brain substance; but twenty-five years ago its age-incidence was often adduced to prove its non-syphilitic origin.

It has been stated often enough that all speculative thinking is to be deprecated, but experiment without speculative direction is like firing without aiming, and accordingly one may shamelessly state what one considers the parasite should be like, for in this case to use a mathematical similitude we have one incognitum to solve and numerous equations to do it with.

Accordingly one imagines that "it" would comply with the following conditions:—

(1) Extremely minute, so as to escape recognition under the microscope; and/or stain with great difficulty with the usual methods. As a third hypothetical alternative it might closely resemble some well-known cellular element so as to be easily mistaken.

Not artificially cultivable on ordinary bacteriological media.

For evident reasons, it does not seem possible that so many years of intense microscopical and bacteriological observation should not have detected any recognizable typical structure.

(2) Should be strictly specific for one sort of cell and multiply in those cells only.

Why? Because malignant growths though very numerous and varied, are true to type and even the most intense infiltration of tissues or the extensive dissemination of metastatic deposits never gives rise to tumours different from those of the original growth; in fact real "mixed" tumours are very rare.

(3) Its pathogenic properties should vary within wide limits and it should be capable of remaining quiescent, smoulder for several years and then flare out afresh.

Examples: The sudden acquisition of pathogenic properties in moles (melanotic carcinoma) or chorio-epithelioma; late recurrences.

(4) Not sufficiently toxic to produce necrosis and degenerative changes in cells, but rather providing a persistent, mild, irritative stimulus capable of inducing boundless cell-division, therefore probably intra-nuclear and not very abundantly present.

A toxic microbe or one multiplying freely would easily lead to cellular necrosis, caseation or at least marked inflammatory reaction. The former (caseation) is unknown in cancerous growths, the latter very moderate, much of the small round-celled infiltration seen round cancer nodules being probably or possibly due to pressure.

(5) Not easily isolated from cellular elements, either by cultivation, filtration, diffusion, centrifugation, desiccation or any other usual laboratory method. On the other hand very resistant when bound to its cells, because cancer cells will stand freezing with liquid air and yet be transplantable, as repeated experiments with mouse carcinoma have proven.

These properties would produce only a low infectivity, because under ordinary circumstances the wholesale scattering of intact cancer cells does not appear probable. And, as a result, though the accumulation of cancerous disease has been noted in certain households, still the development of the growth has usually taken place at such intervals (but in the same surroundings) that a direct or personal contagion is not easily deducted or proven, for the infection (if any) may equally well be connected with the building and not the individual.

(6) Therefore similar in this, and probably this only, to the germs of actinomycosis and tetanus which are fairly ubiquitous in nature, but yet do not cause disease in man or animals till they obtain not only an entry but special conditions favouring parasitic multiplication.

(7) Unlike tetanus and actinomycosis (and one might add certain leptospiræ) the parasite of cancer need not be ubiquitous in nature in the sense of its "sapropelic" occurrence, for numerous conditions exist in which individuals may harbour a protozoon, protist, mycete or bacterium, all of them closely allied to pathogenic varieties (and in some cases actually indistinguishable from those causing serious diseases) and yet appear in perfect health.

It therefore might be ubiquitous in the sense of being widely distributed not necessarily in the wide wide world, but as occurring in all vertebrates or perhaps being found consorting in different varieties with all forms of life.

These seven points have already been published in the *South African Medical Record* of Capetown (1925), and at the time I stated that one type of micro-organism and one only could comply with these conditions and that a microplasm, following by giving particulars of the appearance of Plimmer's bodies in cancer. The reader who is interested is referred to the paper in question; but as a personal note I may mention that in the course of time the growing conviction that malignancy if not "parasitic" in origin was connected in some fashion with the appearance of certain peculiar definite corpuscles of the nature of Negri's bodies in rabies, made me relinquish medical practice at the end of 1924 to dedicate myself to the experimental proving or disproving the theories I had formed on the subject.

With great interest, therefore, I found that L. W. Sambon had published in this Journal in the issue of February 2, 1925, the following views, the outcome of

numerous epidemiological researches in Romagna and other parts of Italy and Iceland :—

"Whatever be the rôle of parasitic worms, the actual, the essential course of cancer is some ubiquitous micro-organism, probably a filter-passer, as the researches of Rous and his fellow-workers seem to indicate," &c.

It is also known how Sambon gives a lucid and most suggestive explanation for the existence of cancer houses by noting the presence of parasitic helminths in experimental and spontaneous cancers of the stomach of rats, and from this logically deducing that the existence of cancer houses is connected with the presence of certain household arthropods, e.g., cockroaches, meal-beetles and also dung-chafers, capable of fostering and disseminating helminthic parasites such as the young forms of spiruroid worms of the genus *Gongylonema*, in addition to the presence of some ubiquitous micro-organism, possibly ultramicroscopic, which, favoured by the irritative activities of the worm, may invade the tissue cells and give rise to malignant cells.

His views are mainly based on analogical conditions in elephantiasis, on the experiments of Fibiger, Bullock and Curtis, Borrel and others ; the observations of Borrel and also Askanazy and his own personal investigations in Romagna, Trentino and Iceland. To these the name of Galli-Valerio could be added.

It may be mentioned that Sambon is constantly gathering more and more confirmation of his views on the subject by the only method suitable for such epidemiological studies—that is critical, personal observation—either your own or that of competent and reliable investigators.

Before leaving the subject it should be explained that worms of the *Gongylonema* genus, though widely distributed and parasitic in numerous animals, have so far but rarely been described as parasites of man—four cases in the U.S.A. and two in Italy. Still, the worms are minute and transparent, and may be temporary parasites only, that is, do not thrive in human tissues, but die and set up a condition of aseptic irritation prone to produce a precancerous condition fit for the multiplication of a virus.

It may appear that so far Sambon's views on cancer rest on slender grounds, owing to the few cases of *Gongylonema* parasitism in man, but the relations of helminths only a few years ago would have been considered visionary, and yet a study of medical literature shows that since the publication of Askanazy's cases in 1901 numerous instances of concurrent helminthic parasites and neoplasms have been published, though in private conversation a noted scientist objected to the view that helminthic infection could lead to cancer. "If that were so, how is it that no cases of cancer caused by *Trichinella* infections have ever been reported?" As a matter of fact *Trichinella* was first discovered in 1852 in a case of cancer of the penis, and several cases have been published with such a connection—ten all told thus distributed—three lips, four breasts, one each rectum, pleura, penis, and tongue, all cancers, no sarcoma, and in these as in many other conditions the unpublished cases are probably more numerous than the published, though it must be admitted that *Trichinella spiralis* encapsulates in a fashion which gives rise to but little tissue reaction, and its connection with cancer may or may not be fortuitous.

J. Ewing (1922), a stern opponent of the parasitic theory of cancer, states on p. 123 of his "Neoplastic Diseases": "I rather frequently find trichinæ in cancerous tongues."

Accordingly the attention of medical men working in tropical climes should be drawn to the possible development of cancer or sarcoma in individuals harbouring *Filaria medinensis*.

Evidently not all cases of cancer are due to helminthic parasites any more than the development of sweep's-cancer covers the whole problem. Sambon's views are meant to be an explanation of the incidence of cancer in certain houses and districts, and even so they postulate the presence of a virus capable of producing cancer without the aid of helminthic parasites, given other suitable circumstances.

XII.—Rous Fowl Sarcoma and Similar Viruses: Their Relationship to Oncology.

The prolonged and intensive investigation of the Rous fowl sarcoma group of filtrable viruses has resulted in a series of valuable observations which eventually will be useful in guiding the study of analogous neoplasms in mammals. Indeed at the present moment a sarcomatous disease of the mouse is being experimentally investigated by the Imperial Cancer Research Laboratory. The observation that tissues of this sarcoma when kept for ten days in glycerine are still capable of infecting, leads one reasonably to expect the presence of a filter-passing virus.

That viruses may play an important part in the production of malignancy has only just begun to be recognized, and the conclusions of a previous paper in the *South African Medical Record* (December, 1925) are refreshed and fortified by the following recent observations :—

(1) The conclusive transmission of warts and condylomata by filtrates after an incubation of months ; for the resemblance of warts and certain carcinomata has puzzled many investigators.

(2) The analogical observation of the property of certain viruses in causing cell-proliferation (epitheliosis contagiosa, Rous fowl sarcoma, the virus of warts, vaccinia in the rabbit cornea, some herpetic viruses).

(3) The discovery of a mammalian sarcoma due to a filter-passing virus.

It is true that as yet—but only as yet be it noted—tar-carcinomata can solely be transmitted by cell grafts and that filtrates are inert, apparently even if inoculated in a so-called pre-cancerous condition, but against this there are the observations of Alexis Carrel who has found a "filtrable principle" in sarcomata produced originally by diverse irritative agents such as tar, arsenic, and indol in fowls and

experimentally proved that this filtrate will reproduce the neoplasm.

Carrel considers that this "filtrable principle" is not a "virus" and that the sarcoma is to be considered as a general tissue reaction, similar to inflammation and suppuration which can be produced by numerous bacteria and also by chemical agents.

Carrel being a scientist of international reputation, his views must be fully considered before being rejected, but it can well be imagined that here we are dealing with circumstances very similar to those relative to the study of Twort's bacteriolysin, which, as we know, is also very difficult to distinguish clearly from an enzyme with the faculty of multiplying.

This can be explained by a rough comparison: the observation of two buckets being emptied, one containing fine dry sand, the other silt. It would be difficult at a distance to distinguish the liquid and the granular substance by sight, and definite evidence could be obtained only by touch or near examination.

Accordingly when one considers living protoplasm whose size is apparently slightly above that of an albumin molecule it is difficult to make a clear-cut distinction from many other similar substances and one can only take as a guide the sum total of the observations of many different investigators.

It cannot be denied that there exists already a series of experimental results and clinical observations proving that cell proliferation approaching that found in malignant growths can be induced by viruses we know. In addition three common properties of microplasms require special attention in connection with cancer-studies:—

(1) The tendency to multiply and express pathogenic properties in previously irritated surfaces.

(2) Long periods of latency followed by outbursts of virulence.

(3) The possible enhancement of virulence by repeated transference.

The clinical applications of (1) and (2) are self-evident. (3) requires a short explanation.

Experimentally we know that vaccinia or a virus of the herpes group from man can by frequent and repeated inoculations from one rabbit to another be rendered so virulent for the rabbit that whilst initially we required a given quantity to bring about fleeting pathological symptoms, in course of time a hundredth or even a thousandth of the original dose will produce severe lesions. Admittedly one can also enhance the virulence of bacteria for certain animals, but to a much less extent.

Now microplasms are above all obligatary intracellular parasites, and it has struck me that a virus accidentally invading cells and which, owing to regenerative processes, was in a state of fairly frequent division following cellular necrosis and sphacelation, would find itself in similar conditions of frequent transplantation from one cell to another, thus renewing its youth and increasing its virulence, enabling it to invade rapidly a great number of cells.

As a matter of fact, growths of the type of Rous fowl sarcoma and also Jensen mouse cancer are both capable of increasing their virulence in the same fashion. Clinically such an increase is not alway evident, because human cancer is not transplanted but who has not observed the rapid growth after a incomplete operation? It seems to me that th opening up of vessels and lymph spaces does no wholly explain the phenomenon, but that possibl active cellular regeneration is preparing suitable soi for a rapid multiplication of the virus in suitabl epithelial cancer cells.

One can attempt to place the whole matter in nutshell with the following statements:—

(*a*) Human and animal warts have been experi mentally proven to be due to filtrable viruses.

(*b*) In fowls sarcomatous growths, both spontaneous and produced by irritants or due to filtrable virus, have been extensively studied; in the mouse similar spontaneous growths have just been recognized.

(*c*) Helminthic parasites have experimentally given rise to malignant neoplasms in the rat and rabbit In man similar clinically and microscopically accurate observations have been reported.

(*d*) Filtrable viruses (microplasms) show a common tendency to develop their pathogenic properties in definite cells of irritated or injured tissues.

(*e*) The presence of chlamydozoic bodies in human cancer and mouse-tumour either postulates that an innocuous virus is multiplying within their cells, or that these neoplasms are due to a virus. A third alternative, that these bodies are figments or artefacts cannot be as stoutly upheld as it would have been some years ago.

(*f*) Not all viruses can be readily or easily isolated by filtration. In some cases, especially when dealing with viruses which are scantily present in tissues, not every experiment succeeds.

(*g*) The unsuspected ubiquitous presence of viruses of the herpetic type removes a great theoretical difficulty which stood in the way of cancer being considered a parasitic disease, and this for reasons already discussed.

(*h*) Precancerous conditions in the skin, where they can be easily observed, can be multiple, and then the corresponding basal-celled carcinomata can arise from multiple foci, thus pointing to the paramount importance of the irritative factor.

These eight statements are founded on easily ascertainable and repeatedly observed clinical, microscopical and experimental facts—and therefore they may justify the deduction of certain views on the causation of cancer, even though they may appear unfounded or even phantastic to many. The essential point, however, is that they should be correct.

XIII.—Specific Properties of Microplasms and their Classification.

A survey of the literature shows that many filtrable viruses have common features, and are fairly consistent in their pathogenic actions, habitat and general properties; thus sufficient is known to enable one to separate biologically a virus which has been accurately studied from a protozoon or bacterium, though admittedly the group thus formed has certain affinities in

behaviour to spirochætes, but even so clear-cut differences can be made out.

A definition or classification of the genus may appear still premature, for we know that leptospiræ are capable of retaining their pathogenic properties after passing filters, and yet cannot properly belong to the group of micro-organisms which cause foot-and-mouth disease in cattle or mosaic disease in various plants, to mention the two first recognized and investigated. On the other hand recent research renders extremely probable the inclusion among viruses of the bacteriolysin first discovered by Twort in 1915.

As a result we have to exclude micro-organisms which are definitely filtrable (leptospiræ), keep in abeyance others whose filtrability is yet subject to discussion (rickettsia), and then include certain peculiar bodies parasitic in living bacteria, which some competent observers are inclined to consider enzymes, and not particulate micro-organisms.

In addition, and here we are treading where others fear to look, it is well within the realm of possibility that viruses exist very similar in many properties to those known as filter-passers, but which, owing to size and protoplasmic constitution, are incapable of retaining their pathogenic properties in the filtrate. It may be possible in fact to form a small group of such viruses of which some members are filtrable with difficulty, and some not at all, but yet sufficiently related in their actions and reactions to require distinct and separate consideration. Experimental proof of these views is being attempted (December, 1925), but in the meanwhile for the purpose of critical review the viruses have been arranged according to the organisms they invade or consort with, and only those definitely filtrable have been considered.

The general properties of microplasms have been discussed in a previous chapter, in which it was shown that invisible in this instance really meant "microscopically indistinguishable," and that this criterion could not be used, either alone or with that of filtrability, as a distinguishing sign in the classification or diagnosis of viruses, as both are factors of size.

The literary survey has made it evident that neither geographical distribution nor occurrence can be used for the same purpose; because microplasms are known to be independent of clime and longitude and have been so far described as parasites of bacteria, plants and vertebrates, and no doubt the list will soon be extended to other forms of animate Nature.

Bacteria, mycetes, protists and protozoa are identified by their morphology in the first instance, and then by the sum of their behaviour under varying conditions, the majority being observations of artificial cultures *in vitro*.

Both these methods fail us with true microplasms, and therefore we must concentrate on observations based on the effects produced in various cellular elements invaded by the virus.

A virus due to microplasms should therefore be distinguishable by the following actions and reactions.

(I) *Parasitism.*

Obligate and selective parasitism of definite living cellular elements. Can survive over long periods by consorting with similar cells, but does not multiply outside a certain selected cellular host.

(II) *Experimental Transmission.*

Can be transferred till infinite dilutions (10^7 and more) are reached and yet pathogenic effects produced in suitable receptive animals—this in distinction to certain powerful toxins.

(III) *Natural Infection.*

Usually by mediate or immediate contagion. Insect vectors usually purely mechanical.

(IV) *Cultivation in vitro.*

Not artificially cultivable on ordinary or slightly modified bacteriological media. This excludes the virus of pleuro-pneumonia, which has bacterial affinities.

(V) *Isolation by Filtration, &c.*

Intracellular occurrence in certain definite tissues, but can be separated from them without losing pathogenic properties by trituration, centrifuging, diffusion, filtration, maceration, hydrolysis or similar methods.

(VI) *Selective Cytotropismus.*

When inoculated intravenously, intraperitoneally or corneally in a receptive animal will cause alterations in certain tissues only—usually if these are previously irritated (erethismus).

(VII) *Vitality.*

Will resist desiccation (and in some cases also subsequent pulverization of cell-host), mild antiseptics, saponine, easily destroyed by permanganate of potash (oxidation).

(VIII) *Thermic Influences.*

Resist freezing even with liquid air—usually killed or considerably attenuated by heat of or above 55° C. for an hour.

(IX) *Chlamydozoic and Strongyloplastic Bodies.*

Many are apt to cause the appearance of a peculiar intracellular reaction in the shape of oval and round fuchsinophil bodies, which are usually not very sharply defined from the surrounding protoplasm.

(X) *Infectiousness.*

Varies within wide limits, may be limited to one genus or species of plant or vertebrate, or may multiply in several, then as a rule producing in all very similar cellular alteration.

(XI) *Incubation.*

Also variable in vertebrates—some as short as five days, others extending to months (warts = verrucæ).

(XII) *Latency.*

Long periods of latency or cryptic subdued multiplication possible with all viruses which have been studied from this standpoint.

(XIII) *Immunity.*

(*a*) *Passive.*—Lasting in the "pock" group, but variable in others. (*b*) *Active or experimental immunity.*—Obtainable in various fashions and different degrees with all viruses known. (*c*) "*Cross-immunity*" experiments possible for the identification of viruses. (*d*) *Polyvalent and irreversible immunity.*—Observed so far only in vaccinia-variola. Vaccinia immunizes against variola, but variola does not immunize specifically against vaccinia. Vaccinia immunizes also against alastrim (milk-pox) but not vice versa, at least not completely; in fact, extraordinary to relate, vaccinia though a strictly localized condition seems to immunize better against alastrim and small-pox than the viruses of these diseases. (See M. H. Gordon, Special Report No. 98.)

(XIV) *Cellular pathogenicity.*

Three degrees of intensity distinguishable, which may occur singly or be mixed in the same infection.

First degree (subpathogenic). Similar to the irritative action of a finely emulsified foreign body, but continuous; resulting in the extensive proliferation and multiplication of certain definite cell-elements. Examples: Rous fowl sarcoma; verrucæ.

Second degree. Resembles toxic action to a certain extent; the cell is usually eventually killed, but during a certain time limited rarefaction followed by vacuolization are the predominant features, together with perivascular round-celled infiltration.

Third degree—rapid colliquation, necrosis, often with the aid of certain bacteria; example, variola.

(XV) *Toxins.*

Production of toxins in some viruses probable, but in all cases presence or absence difficult to prove for evident reasons.

(XVI) *Virulence.*

This often decreases in the course of transmission from one animal to another, but it can be appreciably increased in various fashions, among the principal being frequent transmission at height of infection and addition of inactivated virus.

(XVII) *Ubiquitous attenuated viruses.*

This heading not sufficiently descriptive, but meant to draw attention to the frequently experimentally proved observation that, analogically to what has been observed with bacteria, concurrently with the epidemic or epizoic spread of an exceedingly pathogenic virus, very similar attenuated strains may be found infesting, more or less harmlessly, the tissues of various animals or individuals; often even after the epidemic or epizoic has died out, the attenuated viruses are still detectable in different individuals—perhaps even permanently.

These characters of microplasmic viruses have been arranged with a view to their distinction from protists or protozoa, bacteria and toxins, all of which under circumstances can cause symptoms easily confused with those due to filtrable viruses; they are also mostly the results of observations made on warm-blooded animals, yet with certain variations they will be found applicable to the virus-diseases of plants and also bacteria.

The list supplies a key to identification which should render recognition possible in suitable instances, and give a basis for a workable classification.

Von Prowazek in 1907 grouped several together as Chlamydozoa (from χλαμυς = mantle), in view of their peculiar property of causing a definite cellular reaction which results in the formation of bodies variously named, such as Guarnieri's (vaccinia), Negri's (rabies), v. Prowazek-Halberstädter (trachoma), molluscum-bodies (discovered by Henderson and Paterson), Borrel's (clavelée, and also fowl-pox), and many others.

Later (1912), von Prowazek divided the Chlamydozoa into three groups, according to whether they consistently attacked the nucleus only, or the protoplasm, and as a third alternative whether they invaded both, and differentiated a further group which he called the Cyto-oikon-group (from οἶκον = house) which caused chronic diseases of the epithelium, not by destroying it, but rather by exciting its proliferative properties.

Lipschütz reviewed the subject in 1913 and some time before, in 1908, had noticed that even smaller bodies than the ordinary Chlamydozoa could be microscopically detected, which through coalescing or aggregating formed Chlamydozoa. These round, minute bodies he called Strongyloplasmata (from στρογγυλο = round), and included among them also the microbe of peri-pneumonia of cattle.

He then published a schema for classification of the filtrable virus, dividing them in two groups: the first comprising acute generalized infectious diseases, this consisting of eighteen viruses among which he placed yellow fever, Rocky Mountain fever, heart-water, virous myxomatosum of rabbits, scarlet fever and measles. This group is at present obsolete for various reasons.

The second group, that of viruses with prevalent localization in definite organs and tissues, is subdivided again into five lesser groups, and as this in the main still holds good, it shall be translated in its entirety.

I.—*Localized epidermal or epithelial.* (1) Molluscum contagiosum, (2) Warts (verrucæ), (3) Trachoma.

II.—*Dermotrope.* (1) Vaccinia-variola, (2) Foot-and-mouth disease, (3) Fowl-pox, (4) Sheep-pox, (5) Stomatitis bovis papulosa specifica, (6) Alastrim.

III.—*Neurotrope.* (1) Rabies, (2) Poliomyelitis, (3) Geese-pox, (4) Guinea-pig paralysis, (5) Distemper, (6) Aujeszky's disease.

IV.—*Hæmotrope.* (1) Fowl leukæmia, (2) Pernicious anæmia of horses.

V.—*Organotrope.* (1) Peri-pneumonia, (2) Agalactia contagiosa, (3) Myxoid disease of rabbits, (4) Epidemic parotitis (mumps).

This includes all diseases which were known at the time to be due to filter-passing viruses and a few which were only suspected as such, and also some which investigation has in the meanwhile shown could and should be arranged in a group by themselves, such as the leptospirosis diseases and those connected with *Rickettsia* bodies.

Even so, the grouping is definitely useful, and one can imagine it will serve as a foundation of an

classifications which will be suggested later as a result of increased knowledge of the subject.

Philibert, 1924, based his classification evidently on that of Lipschütz, but with a certain echo of the opinions of von Prowazek in the cytolytic and cytokinetic groupings induced by the evident affinity or cytotropismus of filter-passers for certain cellular elements.

He divides viruses accordingly into two main groups, and then subdivides them in the following fashion according to their predominant affinity :

(1) *Cytolytic.*

(*a*) Epithelial affinity (epitheliosis). (1) Foot-and-mouth disease ; (2) Variola ; (3) Vaccinia ; (4) Sheep-pox ; (5) Variola des chiens ; (6) Herpes.

(*b*) Nervous system (Neurotropes). (1) Lethargic encephalitis ; (2) Rabies ; (3) Mumps.

(*c*) Endodermic (?). (1) Hog cholera ; (2) Fowl-diphtheria.

(*d*) Mesenchymatous. (1) Pernicious anæmia in horses.

(*e*) Microbes. (1) Bacteriophage (Twort's bacterio-lysin).

(2) *Cytokinetic.*

(*a*) Epithelial. (1) Trachoma; (2) Molluscum contagiosum ; (3) Fowl-pox ; (4) Warts.

(*b*) Mesenchymatous. (1) Fowl-sarcoma.

This is evidently only a tentative sketch, because it separates identical viruses under two headings, leaves out all plant viruses, and does not cover more than a small portion of the known viruses, which now number well over fifty ; if one adds to these the diseases where there are good reasons to believe that they are caused by a filter-passing virus, the number would reach the century. Accordingly in this paper only the principal and best known viruses have been mentioned and they have been arranged according to a definite and conclusive criterion—their occurrence and transmission in nature, a matter about which there can be but little disagreement.

XIV.—Conclusion.

Even these necessarily incomplete notes show the extent and importance of the study of filtrable viruses or microplasms. The ground already covered and definitely secured by experiment and observation would by itself be sufficient to arrest attention ; much greater are the possibilities which we can begin to perceive.

It is usual to include scarlet fever and measles among diseases due to filter-passers, and though single experiments have succeeded and chlamydozoic bodies been described in these diseases, the evidence so far available is not sufficient for clinical application.

Also chicken-pox, herpes zoster, alopecia areata, certain leukæmic types of blood diseases, possess the habitus of infections due to cytotropic cell viruses, because pathological alterations are so strictly limited to one type of cell. Their definite addition to the group, however, must be postponed till more evidence is available, though also here single experiments have been reported showing the possibility of isolating a filtrable virus from some of those diseases.

Proof positive usually fails owing to the fact that human infections with filter-passers are as a rule only experimentally transmissible to human beings, especially if the corresponding clinical symptoms are to be faithfully reproduced.

It may appear that the same could be said of malignant neoplasms, but in this case we are dealing with a big group of viruses, conclusively present and easily isolated in certain animals, and it is only a question of extending the knowledge thus acquired to the more intensive study of cancer in man and animals along certain lines of purposive experimentation.

We are but beginning to obtain a knowledge of these micro-organisms and their properties, and if we but cast our thoughts back in the study of syphilis or tuberculosis during the last fifty years, we can perceive on what lines advance is to be expected. A Frenchman said in the last century that the cause of cancer, syphilis, tuberculosis and original sin was an indissoluble "quadrille", which would defy our efforts to make them dance to a tune of our choosing to the end of time ; witty man, but indifferent scientist.

Molteno Institute of Research in Parasitology.
December 20, 1925.

Syphilitic Pseudo-Elephantiasis. — Dr. H. MacCormac showed, before the Dermatological Section of the Royal Society of Medicine, on June 18, 1925, a case of syphilitic pseudo-elephantiasis in a man, aged 73, who gave the following history : Seven years ago he was suddenly attacked with severe pain in the back, and the left foot, leg and thigh became swollen and œdematous. About three years later what he describes as two ulcers (in reality gummata) developed in the left thigh. A varicose condition then developed over the left abdomen, thigh, scrotum and penis, indicating further obstruction of the deeper veins of the thigh or pelvis. No other symptom occurred until about a year ago, when the elephantiasis lymphatic varices and ulceration developed in the left leg.

On admission to hospital the following condition was observed. Enlarged veins were present in the left abdominal region, thigh and scrotum. Two pigmented scars marked the site of the former gummata; the left foot and leg were swollen, and lymphatic varices in the form of papillomata were present about the ankle. In this area there were two small ulcers. Treatment by rest, bismuth injection and potassium iodide produced considerable improvement.

The exact nature and position of the venous obstruction are difficult to determine. Although the Wassermann reaction was strongly positive, no history of syphilitic infection could be obtained. The history of the sudden pain in the back with swelling of the leg, suggests a thrombosis at that time, but the later and more considerable changes directly followed the gummatous development in the left thigh.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—**All literary communications should be addressed to the Editors.**

4.—**All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE.** Cheques to be crossed The National Provincial Bank, Ltd.

5.—**The Subscription, which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

JANUARY 15, 1926.

THE RELATION OF FRAMBŒSIA TO SYPHILIS.

IT has been held by some authorities that frambœsia is to be looked upon as a form of syphilis, and this view has been the subject of discussion ever since the two diseases simultaneously first began to engage the attention of European physicians soon after the discovery of America; and prominent amongst modern syphilographers who have supported this theory stands the name of Sir Jonathan Hutchinson. That the clinical course of frambœsia shows a certain parallelism to that of syphilis would afford some support to this view. Thus, in both affections, after a period of incubation, usually of some weeks' duration, and often characterized by signs of malaise, rheumatoid pains, headache and irregular rise of temperature, the primary lesion appears at the seat of inoculation or infection. This primary stage is followed in both diseases by a secondary stage in which the characteristic eruption occurs, and then by a tertiary or late stage in which the late manifestations of the disease develop, namely, deep ulcerations and gummatous nodules. A fourth period may also be added, named respectively parasyphilis and paraframbœsia. In both diseases alike this division into three or four stages is somewhat arbitrary, as symptoms characteristic of one period may be encountered in another stage. Again, there are a certain number of cases of both diseases showing periods of latency in which the patient is apparently free from symptoms but sooner or later shows renewed manifestations of the infection. In the case of syphilis this latency has often been emphasized in recent years by the findings of the Wassermann reaction.

That frambœsia and syphilis, however, are two different maladies was proved by actual experiment in 1882 by Charlouis. The discovery of the different causal organisms—the *Treponema pallidum* of syphilis by Schaudinn, 1904, and the *Treponema pertenue* of frambœsia by Castellani in 1905—established the modern view of the separate identity of the two diseases. In further support of this view it may be pointed out that in frambœsia the seat of the primary lesion is always extragenital, whilst in syphilis an extragenital primary lesion is so rare as to be almost a pathological curiosity. Many ætiological considerations also point in the same direction. Thus, in frambœsia sex does not exert any influence, nor does age to any great extent, though the disease occurs most frequently in children and young people. Insanitary conditions also to a certain extent favour the development and dissemination of the disease, the malady being rare among Europeans and the better class natives who live amidst good sanitary surroundings, and common among villagers and low-caste natives who live in uncleanly overcrowded huts.

The geographical distribution also differs. Thus, syphilis is world-wide, anl no climate or race is free from it; whilst frambœsia is essentially a tropical disease, few, if any, genuine cases having been reported outside the tropical and subtropical zone, and even in the tropics it is never found in the mountains or in cold districts. Even within the tropics the distribution of frambœsia is patchy. Thus it is extremely frequent in Ceylon, but very rare in India.

The results of inoculation of monkeys have been brought into this discussion. Monkeys have now been successfully inoculated with frambœsia and with syphilis, and many observers have shown that monkeys successfully inoculated with frambœsia do not thereby become immune to syphilis, nor do monkeys successfully inoculated with syphilis become immune to frambœsia, although Levaditi found that the latter animals may acquire a partial immunity to frambœsia. Further, monkeys of the species *Cynomolgus philippensis* are susceptible to frambœsia but not to syphilis.

Inoculation experiments have also been performed in men. Frambœsia may readily be produced in this way, and patients so suffering have been successfully inoculated with syphilis. Nor are frambœsia patients immune against syphilis, as proved by published case reports; and conversely syphilitic patients may contract frambœsia naturally and experimentally. In a recent report, however, Jahnel and Lange (*Münchener medizinische Wochenschrift*, August 28, 1925) tried to infect with the frambœsia spirochætes four persons with general paresis, and failed. They attribute the immunity shown by their cases to the close biological relation which exists between the spirochæte of syphilis and that of frambœsia. This close biological relationship is further shown not only in the close morphological similarity of the two organisms but by the reactions they excite both in the tissues and body fluids of infected persons. The similarity of these tissue reactions places both diseases into the group of the infective granulomata, whilst the similarity in the reactions of the body fluids is shown by a study of the serological reactions. Thus the Wassermann reaction is positive in the great majority of recent cases of frambœsia, though it is frequently negative in old cases. According to Schüffner and Violle, in frambœsia there is often fixation of complement if an alcoholic extract of syphilitic liver is used as antigen, but there is no fixation with an aqueous fixation. Again, the cuti-reaction with "frambœsin," a preparation of *T. pertenue*, is often positive, whilst luetin may also give a positive though less marked reaction. Finally, the action of spirochæticides such as neosalvarsan is rapidly destructive of both organisms, the *T. pertenue* being particularly susceptible.

Annotations.

Tuberculosis in the Tropics (Sir James Kingston Fowler, *Proceedings of the International Conference on Health Problems in Tropical America*, 1924).—Sir J. K. Fowler points out that tuberculosis may not loom very large in the curricula of schools of tropical medicine, but diseases refuse to be specialized and assert their right to world-wide prevalence, and to this law tuberculosis is no exception. He also considers that the features of tuberculosis as it occurs in the tropics have to do more with the inhabitants, with their past history in relation to it, and with their housing and mode of life, than with the climatic conditions that are peculiar to tropical countries. When tuberculosis is first introduced into a country previously free from it, the natives undoubtedly exhibit a degree of resisting power much inferior to that possessed by inhabitants of countries in which it has been prevalent for generations. It would appear that tuberculosis is on the increase among the native inhabitants of most of the British tropical dependencies. Administrative measures for dealing with tuberculosis, either in the tropics or elsewhere, depend upon accurate diagnosis of the disease, and the only *positive proof* of that disease is the finding of tubercle bacilli.

With regard to notification, Sir James states "whether or not notification of tuberculosis should be enforced must depend, in the tropics, upon the local conditions and upon the degree of civilization to which the people concerned have attained. It is useless if the notifications, as is too often the case, are received only a short time before the death of the patient or after his decease. The value of notification, apart from statistical inquiries, depends on the use that is made of it in dealing with contacts and in removing them from unhealthy surroundings." Further, "My advice to any colony disposed to grapple seriously with the tuberculosis problem," he says, "is to destroy its slums and start a tuberculosis settlement on the lines which I have herein suggested."

Such a Tuberculosis Settlement would comprise: (*a*) ***Diagnosis Ward***, into which all patients should be admitted, and remain until the diagnosis has been settled. (*b*) ***Clinical Ward***, for cases requiring close observation. (*c*) ***Operating Theatre and X-ray Installation***, for the performance of artificial pneumothorax and thoracoscopy. (*d*) ***Sanatorium Block***, for patients going through the usual sanatorium course, but in whom the disease is not yet arrested. (*e*) ***Hospital*** for advanced cases and those who break down when engaged industrially. (*f*) Huts for patients on leaving the sanatorium, as two-bedded, open-air huts are less costly to maintain. (*g*) ***Hostels*** to which patients from the huts may be promoted. (*h*) ***Cottages*** which are reserved for married men. (*i*) ***Workshops***—Training in industries carried on in hygienic workshops involves, in temperate climes, less exposure to climatic conditions which may be harmful, than open-air occupations, but in the tropics such considerations may not apply.

Such a tuberculosis settlement, unlike a colony, within a ring fence forms part of the community as a whole. Main roads may pass through it and its shops are open to all.

"Any country," he concludes, "that rejects compulsory vaccination and retains its slums must pay for small-pox hospitals and tuberculosis settlements. The tuberculosis problem is, to a very large extent, a housing problem in all parts of the

manner. There are normally no distinct pseudopodia. The protoplasmic currents can be seen to flow forward down the middle line of the body, more slowly outward on reaching the anterior end, and gradually backward at the sides. This movement has been well described by Rhumbler in 1912.

It is a characteristic feature that pseudopodia are only extruded apparently under abnormal conditions, as, for instance, when a severe obstacle is encountered, or when the amœba is crushed or placed in saline. Differentiation between the endoplasm and ectoplasm is also characteristically indefinite, but in the above-mentioned abnormal conditions, a clear hyaline layer is sometimes distinguishable as shown in fig. 2. The posterior end of the body, when the amœba is moving forward, is also sometimes quite clear and devoid of inclusions. In the normal state, the relative constancy in shape and simplicity of outline suggest that the body is surrounded by a tough, elastic ectoplasmic covering. The cytoplasm during movement presents a very characteristic appearance of striation, which has been observed by all writers. Janicki's impression was that the protoplasm actually consisted of threads embedded in a more refringent jelly-like mass; Mercier, on the other hand, interprets the appearance as the effect of currents in the protoplasm. This is probably the true explanation, since no trace of them can be seen in resting or stained individuals. Leïdy states that the cytoplasm is ordinarily without inclusions, but these are numerous when the contents of the gut are of a suitable nature for ingestion. Each is usually contained in a food vacuole as shown in fig. 1.

The foregoing account indicates that in movement, and in the differentiation and striation of the cytoplasm, the species *Endamœba blattæ* is clearly to be distinguished from the *E. coli* group. It resembles them in the absence of a contractile vacuole.

The nucleus of the vegetative form is one of the most distinctive features of the species. It is relatively large, oval in shape, and usually measures in length about 15 or 16 microns, and in width 12 or 13 microns, though Janicki describes it as averaging 18-20 microns in width. In the largest individuals it may be 20 microns long. As a rule it has a characteristic shape which may be seen in figs. 1 and 2, where there is a knob-like projection at the pointed end, an appearance that has been noticed by the earlier observers. It may be the result of nuclear division, the knob representing the original point of connection between the two daughter nuclei. This seems all the more probable in view of the fact that the nuclear membrane is remarkable in being at least 1 micron thick. It is homogeneous, but shows a very distinct double contour.

Within the nucleus there is usually found, in the living state, a quantity of highly-refractile granules, occasionally yellowish in colour as noticed by Janicki. These are arranged in the peripheral zone, sometimes regularly, sometimes more to one side so as to form a crescent in section. The central region is quite distinct and has a hyaline or alveolar structure. In stained specimens there is a more or less distinct peripheral zone consisting of granules which stain deeply with iron hæmatoxylin and with eosin. The zone usually occupies the relative amount of space shown in fig. 1, but is often thinner (*vide* fig. 3). In this region there are always a number of much larger darkly-staining masses of various sizes, usually to be found round the inner margin of the zone (*vide* figs. 1 and 2). They may, however, be scattered throughout it, some of them close to the nuclear membrane as shown in fig. 3. On further differentiation these masses (the nucleoli of Mercier) show a granular structure.

In the centre of the nucleus is a clear area which stains very faintly. This is probably what Leïdy meant by the "nucleolus." It shows, as a rule, a hyaline or very finely alveolar structure (fig. 3). The present observations are in accord with those of Mercier in showing that there is no central mass of chromatin, or any body which might be regarded as a karyosome. Janicki (1908) stated that such a body was sometimes to be seen in sections, but as Mercier explained in 1910 this was probably due to an in-pushing of the granular zone. There is occasionally an indefinite, spongy, achromatinic network faintly stained, in the central zone (*vide* fig. 2). The thickness of the membrane, the arrangement of the chromatin, and the absence of a karyosome are all features contrasting this nucleus with that of the *Entamœbæ*.

Among the vegetative amœbæ described above are sometimes found multinucleated free forms which have been overlooked by all writers except Mercier and Janicki. They were interpreted by the former as initial stages in the process of gametogony, which up till now he alone has described. Amœbæ have been found possessing 2, 4, 6, 7, 8, and 10 nuclei respectively (*vide* fig. 4). There can be no doubt that they were free forms, since, though usually rounded in shape, they sometimes showed indications of pseudopodia (fig. 4), definite food vacuoles containing inclusions, and never any trace of a cyst wall. The multinucleated amœbæ average about 30 microns in diameter. The nuclei are different in structure from those of the vegetative form and much smaller. As Janicki observed they are often irregular in shape and of different sizes. The arrangement of the chromatin is extremely variable, probably because the nuclei are generally in different stages of division. Examples are shown in fig. 4.

The normal cysts appear to be of one kind only and not of two ("dark" and "clear") as described by Elmassian. They vary much in size, but are usually under 50 microns, and may be as small as 25 microns in diameter. The number of nuclei is also very variable, cysts being found with only eight and others with over thirty. Fully-developed cysts have probably never less than twenty. The cyst wall is very thick, and shows distinctly in mounted preparations. The nuclei are smaller than those of the multinucleate amœbæ, but are more like them than the resting nucleus of the vegetative form. Each appears, when stained, as a dark irregular

ring within which are a number of deeply-staining granules. These may be scattered, but are often gathered together loosely so as to form a central mass, which might be interpreted as a karyosome (fig. 5.)

Summary.

A restudy of *Endamœba blattæ* (Bütschli) Leidy, 1879, has brought out the following features which distinguish it from *Entamœba coli* Casagrandi and Barbagallo, 1895.

(1) Movement is normally carried out by a steady flow of the endoplasm, and not by means of pseudopodia.

(2) There is a thin, elastic, ectoplasmic layer difficult to see but occasionally modified to form a clear, blunt pseudopodium.

(3) Multinucleated free forms are fairly common.

(4) The nucleus of the vegetative form has the following characteristics: (a) It is large, often lemon-shaped, and bounded by a thick double-contoured nuclear membrane. (*b*) The chromatin is arranged as a broad peripheral zone of granules among which are several denser masses of a granular nature. (c) The central zone is alveolar, and achromatinic. There is no central karyosome.

(4) Multinuclate free forms are often found.

(5) The cysts, which are common, have nuclei varying in number from eight to over thirty.

Conclusion.

The nuclear structure has already been used to classify entozoic amœbæ into different genera, and the constant features of the nucleus of *E. blattæ*, considered together with the characters referred to above, would seem to merit generic distinction on the same principle. Moreover, there can be no doubt that it was only by accident and through lack of co-ordination that certain observers have come to regard the genus *Entamœba* Casagrandi and Barbagallo as identical with *Endamœba* Leidy.

The question which remains to be settled is whether the two generic names, *Endamœba* and *Entamœba* can be retained, as was provisionally suggested by Dobell (1919).

DESCRIPTION OF PLATE.

Endamœba blattæ (Bütschli) Leidy, fixed in Schaudinn's solution, and stained with Heidenhain's iron hæmatoxylin (figs. 2-5) or Ehrlich's acid hæmatoxylin and eosin (fig. 1). Figs. 1, 2, 4, 5 drawn at a magnification of 1,250 approximately, and fig. 3 at a magnification of 2,400.

(1) Free amœba showing a number of food vacuoles containing inclusions. The nucleus is lemon-shaped and has the characteristic thick membrane. It shows the peripheral zone of chromatin granules on the inner margin of which are lying denser granular masses. The central zone is clear.

(2) A smaller free amœba showing a clear ectoplasm which is not often seen. In the central region is an achromatinic spongy network.

(3) A less typical nucleus than that shown in fig. 1; the granular zone is narrower and the denser bodies are more scattered.

(4) A 10-nucleated free amœba showing a small pseudopodium and two food vacuoles containing inclusions.

(5) A cyst showing the thick wall and twenty-one nuclei, many of which contain a central mass of chromatin granules aggregated in the centre.

A MORPHOLOGICAL AND CULTURAL INVESTIGATION OF *VIBRIOTHRIX ZEYLANICA* CASTELLANI.

By Mario Peruzzi, M.D.
Professor in the Naval Medical School, Naples.

In the autumn of 1923, being in charge of the bacteriological department of the Naval Hospital at Pola, I had the opportunity of carrying out researches on dysentery bacilli found in the hospital cases. The cases were all military men who had never been abroad or in the colonies, neither had any of them previously contracted dysenteric affections.

The bacteriological examination was made according to Castellani's method, which nearly always brought about the isolation of *Bacillus dysenteriæ* Shiga.

In some cases the investigation was rendered very difficult by the presence of numerous colonies of a lactose non-fermenting organism which further investigation proved to be *Vibriothrix zeylanica* (Castellani 1910). Strains of this organism were sent to Professor Aldo Castellani for confirmation of the diagnosis, and he kindly replied that the strains sent to him were identical with his laboratory strains of *V. zeylanica* and with the strain of the Lister Institute.

The principal diagnostic characters of this micro-organism are the following: polymorphic organism, vibrio-like, bacillus-like, spirillum-like, coccus-like, and filamentous forms being also observed; motile, Gram-negative, not acid-fast. No acid fermentation of any sugar; on the contrary there is frequently a production of alkalinity. Milk generally rendered alkaline, at times peptonized.

V. zeylanica was discovered by Castellani in Ceylon in 1904, in dysenteric fæces, and was successively described by the same author under various names (*Spirillum zeylanicum*, *Vibrio zeylanicus*, *Spirobacillus zeylanicus*) on account of its polymorphism. In 1910 Castellani thought fit to create the new genus *Vibriothrix* for this peculiar micro-organism, placing it provisionally with the genera *Leptothrix* and *Cladothrix*, under the Fungi Imperfecti. This name is now generally accepted.

V. zeylanica has also been isolated several times in Europe. It was found in Taranto in 1917 by Castellani himself in collaboration with Spagnuolo and Russo, during their investigations on dysentery in the Navy; they emphasized the point that the colonies of this organism on MacConkey's, Endo's, and other coloured media might be easily mistaken for colonies of true dysentery bacilli. The same micro-organism was isolated in London by Taylor, in 1919, from a patient from Ceylon suffering from chronic dysentery. The isolation of *B. dysenteriæ* Shiga, which had been successful at the beginning of the illness, remained negative, while *V. zeylanica* was found in remarkable numbers.

V. zeylanica was also isolated in Constantinople by Delamare and Alalon, 1922, during researches on refugee Russians from places infected with cholera and dysentery. In an interesting publication in 1923, the authors called attention to the possibility of errors in investigations on carriers of vibrios and in the diagnosis of cholera and intestinal spirochætosis, on account of the vibrio-spirillar form which *V. zeylanica* presents in cultures in peptone-water.

In the same year Jacono reported the isolation of this micro-organism at Naples.

Of the pathogenic action of *V. zeylanica* little has been published. According to Castellani, this micro-organism is not pathogenic *per se*, he considers it to be a nosoparasite. The majority of the strains isolated in Ceylon did not prove pathogenic when inoculated subcutaneously in laboratory animals. The strain isolated in London by Taylor was inoculated without results intraperitoneally in doses of 1 to 2 c.c. in the guinea-pig and rabbit; the strain isolated by Delamare and Alalon was also inoculated without results in doses of 2 c.c. of emulsion from agar culture, subcutaneously and intravenously in the guinea-pig and rabbit, and intramuscularly in the rabbit.

This micro-organism is extremely interesting for its truly singular morphological characters and pleomorphism. Castellani, from the very beginning of his investigation, called attention to the various morphological aspects which the organism may take bacillar, vibrio-like, undulating, spirillar, coccoid and large globular forms, which may be found in the same culture. Taylor, in describing the strain isolated in London, confirmed the characters described by Castellani, and illustrated his work with good photomicrographs of the bacillary and vibrio-spirillar forms.

Anigstein studied a strain of *V. zeylanica* sent by Castellani to the Epidemiologic Institute of Warsaw, and showed with the Zettnow method the presence of very fine cilia in the globular and bacillary forms. When stained with crystal violet and fuchsin he noticed filamentous elements with hyperchromatic segments and alternate clear spaces. In a fresh preparation he also observed the presence of refractive polar granules. Numerous illustrations complete the very interesting paper, showing especially well the situation of the cilia.

Delamare and Alalon, in the two strains isolated at Constantinople, described a more detailed polymorphism, calling special attention to the vibrio, spirochætic, bacillary and filamentous forms of the culture in peptone-water. In their preparations stained with the usual dyes they observed hyperchromatic granules, sometimes situated at one of the poles, sometimes placed in rows. The illustration of the morphological characters is copied from Castellani and Chalmers' "Manual of Tropical Medicine."

The strains isolated by me from cases of dysentery at Pola present all the typical characters of the organism.

(A) Morphological Characters.

Structure of the Micro-organism.—The best method for putting into evidence the peculiar struc-

ural characters of *V. zeylanica* is by staining for 30 to 40 minutes in a 10 per cent. solution of Giemsa. The May-Grünwald method has also given good results. The common, simple stains are less favourable, even if they give on the whole good preparations, especially Roux's gentian violet and carbol-fuchsin. Gram staining is always negative, so is staining for acid-resisting germs, and Neisser's method for spores and metachromatic granules. By using Giemsa staining it is clearly shown that the elements of *V. zeylanica*, whatever their form, attain a very complicated structure; there is a fundamental protoplasm which stains blue, containing chromatic masses of nuclear and chromidial structure which stain purplish-red.

The protoplasm appears homogeneous or slightly granular, at times condensed in masses of lighter and deeper colour. There may be some vacuolization.

Polymorphism.

V. zeylanica is a highly polymorphic organism, but its polymorphism is maintained on definite lines totally different from the irregular degenerative characters so frequent in other bacteria when placed under special biologic conditions. Generally the different forms are found associated, and even in very peculiar conditions of development it is not possible, in my experience, to obtain monomorphic cultures; however, in some cases well-defined elements predominate. The most characteristic forms belong to the following types:—

(1) *Undulating Elements.*—These are characterized by their elongated form and very fine extremities, and by their flexible appearance with two to five large undulations. These are particularly common in broth cultures, and are most evident in the thin pellicle on the surface which often adheres to the wall of the tube. Their dimensions vary exceedingly, from 8 to 15 microns in the smaller forms up to 60 microns in the larger forms. Examined by the hanging drop method, some of them present tortuous movements; some are non-motile. After a few minutes the movements become weaker and cease definitely after about thirty minutes. In stained preparations elements are seen which look very much like protozoa, with their very fine ends and evidence of a nuclear structure, which is generally represented by an elongated, oval mass, staining very deeply, situated in the middle part of the micro-organism. This form, represented in fig. 1, can be considered as typical and completely developed. In certain very frequent forms the protoplasm appears homogeneous, uniform, almost refractory to staining, and contains, besides the central nucleus, numerous spherical bodies possessing the same chromophilic properties as the nucleus (see fig. 2).

Some elements show special particularities which clearly correspond to the various phases of a process of fission. In the phase of preparation, the micro-organism appears larger on account of thickening and contraction of the central protoplasmic matter, which seems to dilate into a bottle shape while the undulations become scarce and less accentuated (see figs. 3 and 4). At the culmination of fission more visible changes take place in the nuclear apparatus, which lead to the separation of two roundish, equal, clearly limited masses (see fig. 5). In the successive phases elements are observed in couples, united by a thin protoplasmic bridge, sometimes hardly perceptible, which keeps together the extremities always occupied by the nuclei resulting from fission (see figs. 3 and 6).

In the hyaline forms the nucleus does not divide into equal parts, but small round bodies originate from each pole, which separate and remain fairly regularly distanced in rows. At the next protoplasmic fission small segments are freed, with nucleated ends, which are probably destined to ulterior development.

(2) *Vibrio-Spirillar Elements.*—These are characterized by their vibrio or spirillar appearance, possessing a certain number of curves. The dimensions vary greatly even in the same culture: from minute, short forms to forms of a considerable length similar to large spirilla. The vibrio forms predominate as a rule in cultures on glucose agar, and also in the first hours of development in broth and other liquid media. The larger and longer forms are observed in the pellicles in broth-blood-media, in condensation fluid, in glucose-blood-agar, and in coagulated blood-serum. The smaller forms are extremely motile; the larger ones move slower and sometimes only show a little oscillation. The smaller vibrioid elements are motile even at room temperature, and in this respect resemble cholera vibrios, although, generally, the curving is less pronounced and the motility less rapid.

The spirillar forms are sometimes present, especially in certain liquid media, only in the first hours of incubation.

Long threads with numerous coils and easily separated in vibrioid elements are observed after three to five hours in blood-broth and in the condensation fluid of tubes of glucose-blood-agar. The chromatic differentiation by Giemsa stain gives them a striped appearance on account of the presence of numerous nuclear bodies of lenticular shape (see fig. 10).

It is interesting to observe the spirillar forms in slant coagulated blood-serum on the fifth to seventh day of development. The younger threads present five to seven coils and can still be seen united in chains (see fig. 11); those more developed look like larger spirillaceæ with fifty or more close, even coils.

(3) *Filamentous and Branched Elements.*—These are characterized by their remarkable length and their filiform appearance with masses of condensed protoplasm deeply stainable, and in parts apparent vacuolation. The chromophilic substance of the nuclear apparatus is found in spherical and cylindrical formations. Sometimes the threads are very long, with a mycelial appearance which singularly recalls that of some nocardiaceæ. Pseudo-ramifica-

tions of the cladothrix type are very frequent, but true **V** and **T** ramifications are also present.

Besides these scarcely clear, branched forms, I have been able specially to observe other more characteristic forms, but not exclusively, in pellicles on certain fluid media. These look so typical and constant that they could be considered as specific manifestations. In their definite aspect they always present a tripod formation, rigorously geometrical, the three parts being at equal angles of 120°. Often such formations have a star-like appearance.

The examination of hanging drop preparations shows the filamentous forms to have a mycelial appearance, without definite movements.

(4) *Claviform Elements.*—These are characterized by their swollen, claviform ends, pyriform or decidedly spherical, varying in size, attaining or surpassing the diameter of 3 to 4 microns. They are frequently found in the pellicles present in fluid media; the clubs become very easily separated from the filaments. In fact, by hanging drop examination and by stained preparations, it is seen how these swollen formations generally detach themselves and complete their evolution as free bodies.

Lateral conidium-like formations are also seen, sessile or sustained by short threads. At times they appear very numerous in cultures in which on the preceding day they were almost absent (see fig. 19).

All the morphological gradations are noted, from simple club thickenings to pyriform or decidedly spherical formations. The younger forms are deeply stained in azure by the Giemsa method; those more developed stain weakly and present small, roundish bodies isolated or flattened, which are stained red-purple by the same method; many of them are very near the periphery and extend to the external surface of the clubs; often small vacuolar spaces are seen in their stead which make one believe there has been an expulsion of chromatic bodies (see fig. 22).

(5) *Globular Elements.*—In all the cultures more or less numerous globular elements are detected. In some cases their numbers are very great in the pellicle formed on liquid media containing blood, and it is easily demonstrated that they were originally terminal or lateral formations of elements more or less elongated, sometimes very small (see figs. 25, 30). Some are very small and have a coccoid appearance, they are uniformly and deeply stained and very likely represent the first phase in the evolution of the spherical bodies; others are larger, attaining a diameter of 1·5 to 2 microns and showing a structure differentiated by the separation of a fundamental substance and of voluminous roundish nuclear bodies, in the shape of a horse-shoe, in wreath-form, &c.; and sometimes they even look like small blastomycetes (see figs. 25, 26).

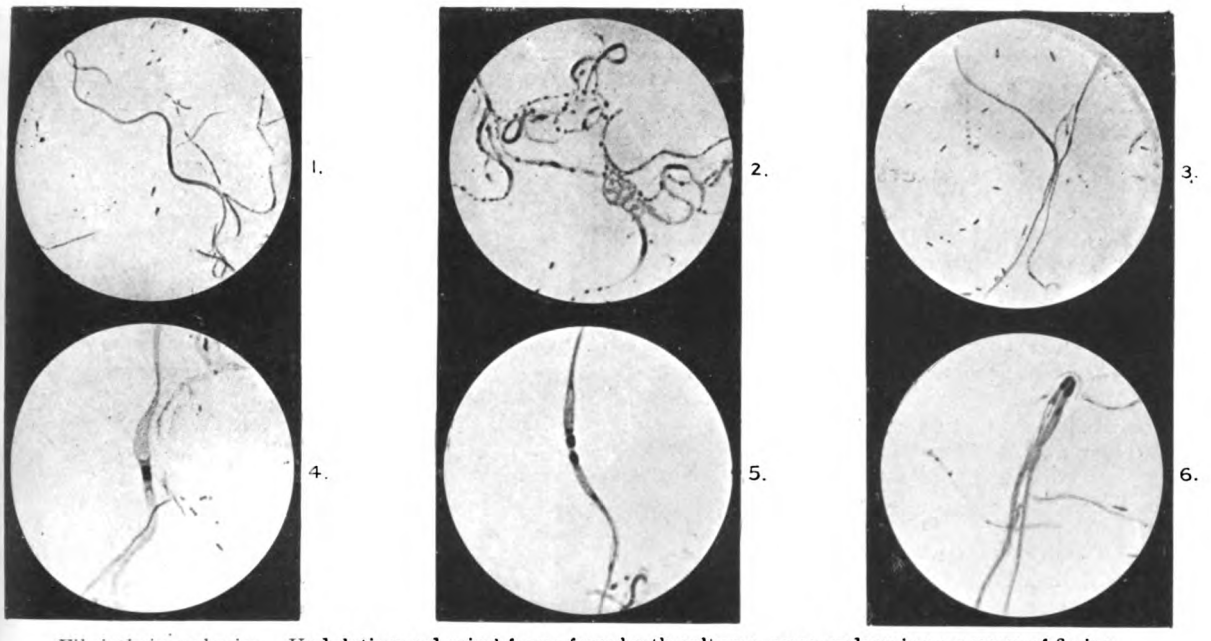
The larger forms can attain or surpass a diameter of 3 microns.

Cultural and Biological Characters.

Cultural Properties.—As already stated, the organism grows well on all the usual laboratory media; the colonies are generally more or less transparent, nearly always round and only slightly elevated. On potato a reddish or brownish pigmentation is often present and this is noted also on gelatine after three to four weeks. A very rapid and abundant growth takes place on glucose agar mixed with 25 to 30 per cent. of human blood. In twenty-four hours there is a beautiful whitish growth, very rich, slightly viscous, with pellicle and abundant deposit in the condensation fluid. Good growth is also obtained in simple broth or glucose broth with 25 to 30 per cent. of defibrinated blood; in twenty-four hours the formation of a surface pellicle is constantly observed, which easily breaks and sinks to the bottom.

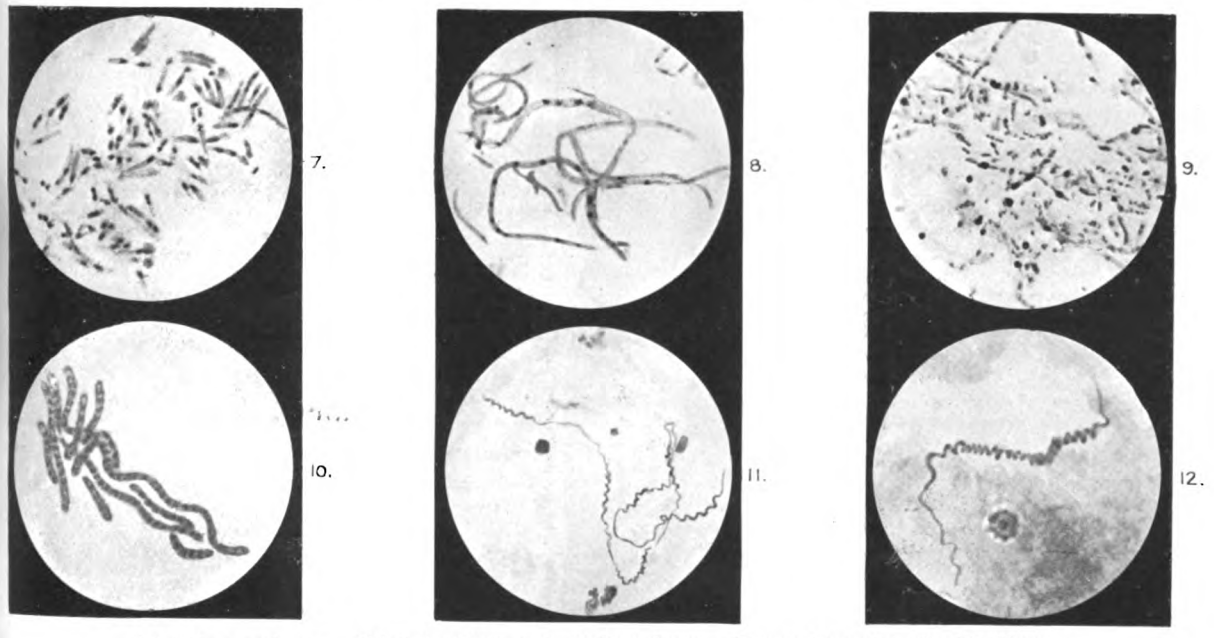
The polymorphism of *V. zeylanica* is not equally manifested in all culture-media; some forms are present almost exclusively on certain media. The undulating forms are found particularly on the pellicle which adheres to the wall of the broth tubes.

Vibrio-like forms greatly predominate in the first hours of culture on fluid media; also in glucose blood-agar. Spirillar elements are very numerous in the pellicle found in the condensation fluid of glucose-blood-agar, and in broth-blood. The spirochætic forms are very numerous in slant cultures with coagulated human blood-serum, after five to seven days' incubation. The filamentous forms are found particularly in the pellicle in ordinary broth.



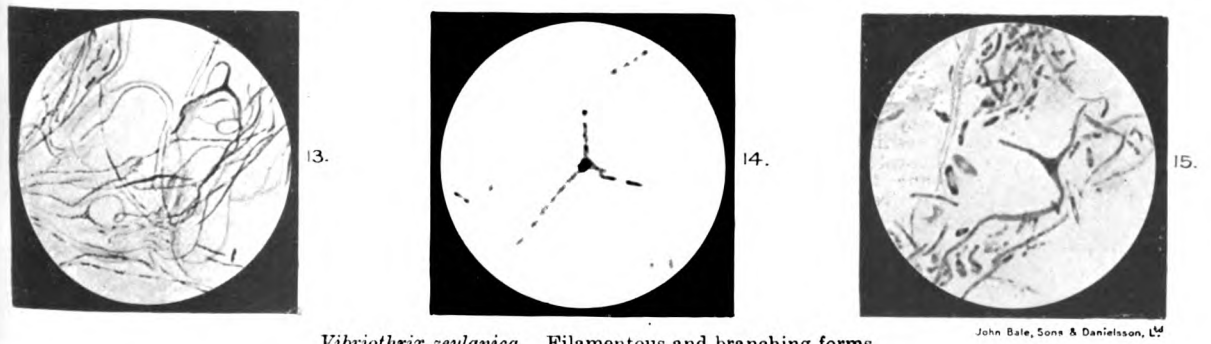
With a view to seeing what form *V. zeylanica* assumes in the intestinal content, I prepared a fæcal emulsion in physiological salt solution which I sterilized at 70° one hour for seven consecutive days. I then added to some tubes 10 to 20 per cent. of heated human serum and inoculated the tubes with *V. zeylanica*. The examination by hanging drop after twenty-four hours' incubation showed elements of *V. zeylanica*, characterized by their special motility and by diverse forms, especially vibrio-spirillar. Inoculating simple emulsions of fæcal matter without the addition of serum with *V. zeylanica* positive results were obtained, but the growth was even and only spirillar forms were observed. The vitality of the *V. zeylanica* culture is remarkable. Ordinary cultures remain alive for more than a year.

Filtrability.



The experiments were carried out using Normayer and Berkefeld N. candles. The filtration was prolonged for ten minutes to an hour. As control micro-organisms, *Micrococcus melitensis* and *Bacillus coli* were used.

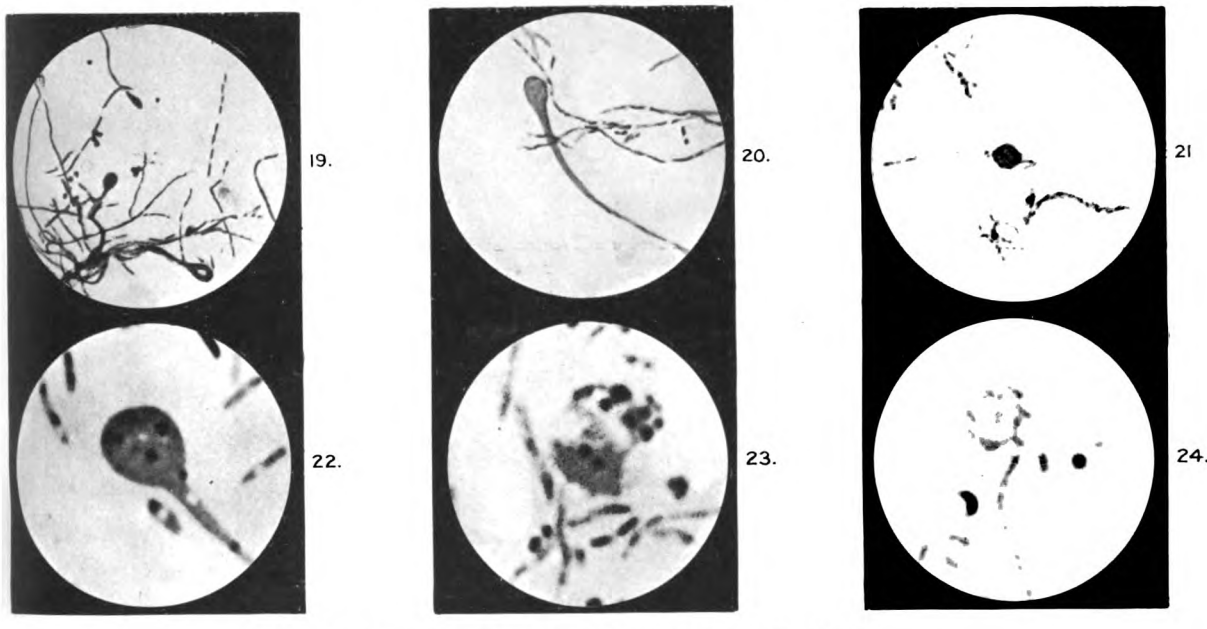
The results were always negative when cultures in ordinary broth were used, but when blood-broth cultures were used then a certain number of positive results were obtained; this would suggest that in blood-broth the organism may produce minute spores capable of passing through a filter.



Pathogenic and Antigenic Action.—For these researches I used guinea-pigs about 350 grm. in weight. Intraperitoneal inoculations of a forty-eight hours' culture at 37° C. on slant glucose blood-agar were carried out. The results obtained so far are as follows:—

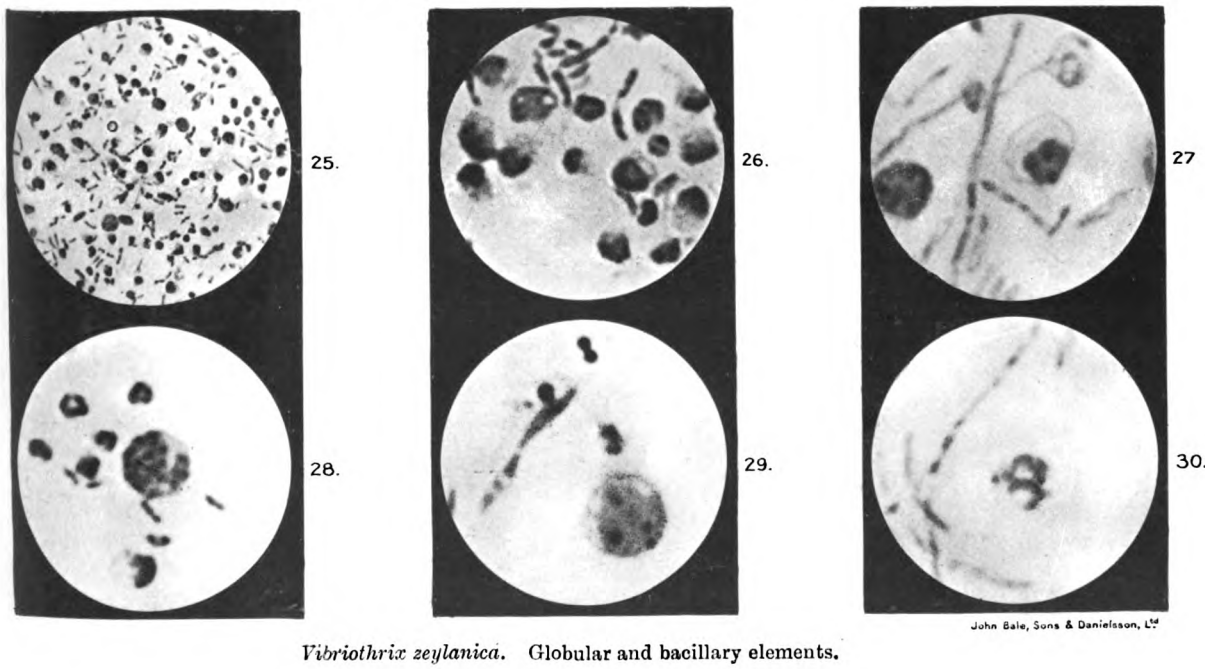
Vibriothrix zeylanica. Undulating and spiral forms from broth cultures, some undergoing a process of fission.

Vibriothrix zeylanica. Vibrio-bacillary and spirillum forms. Preparations stained with Giemsa.



Vibriothrix zeylanica. Filamentous and branching forms.

John Bale, Sons & Danielsson, Ltd.



To illustrate article, "A Morphological and Cultural Investigation of *Vibriothrix zeylanica* Castellani," by MARIO PERUZZI, M.D.

Vibriothrix zeylanica. Filamentous and branching forms.

Vibriothrix zeylanica. Claviform elements and spore-like bodies.

Vibriothrix zeylanica. Globular and bacillary elements.

To illustrate article, "A Morphological and Cultural Investigation of *Vibriothrix zeylanica* Castellani," by MARIO PERUZZI, M.D.

The inoculation of one and a half to two surface growths causes death in thirty hours after a long period of coma. Inoculation of one half to one surface growth is tolerated, and produces transitory troubles with notable loss in weight in the first three to four days. Specific antibodies are already in evidence ten days after the first inoculation by means of the reaction of the Pfeiffer, Bordet-Gengou and agglutination tests in dilution up to 1 : 200; after a second inoculation there are immunity reactions, more marked, with agglutination up to 1 : 500. When *V. zeylanica* is inoculated in the peritoneum in moderate doses it is rapidly destroyed by phagocytosis; in animals previously inoculated a ready lytic destruction is also observed.

The anatomo-pathologic changes in evidence at autopsy are characterized by an intense, acute peritonitis, with abundant thick, fluid exudate and fibrino-purulent stratifications on the abdominal viscera.

In the other visceral organs congestive changes are found; some subpleural minute hæmorrhages and pulmonary œdema are present, which should be considered as terminal phenomena in relation with the long period of the comatose state which precedes death.

Conclusions.—A strain of *Vibriothrix zeylanica* (Castellani) was isolated in the autumn of 1923 at Pola from soldiers affected with bacillary dysentery.

Staining with Giemsa's method puts in evidence the complex structure of this micro-organism and shows the presence of a nuclear apparatus highly differentiated, which plays a rôle in the phenomena of reproduction.

V. zeylanica is an extremely polymorphic organism with vibrio-like, bacillus-like, spirillum-like, coccus-like and filamentous and large globose forms. The cultures obtained in broth-blood are filtrable through Berkefeld N. candles.

The intraperitoneal injection of massive doses causes death in guinea-pigs, while the injection of ordinary doses does not cause death and the organism is destroyed by a process of leucocytosis.

With regard to the classification of the organism the presence of branching filaments and sporiform bodies is in favour of the organism belonging to the Fungi Imperfecti; the rapid growth, the presence in certain media of only bacillary and vibrioforms, its antigenic and immunizing action might be reasons to place it among the Bacteria; the spirochætic elements and the well-marked morphological and chromatic differentiation of the nuclear apparatus are suggestive of protozoal forms.

Owing to these various morphological characters the systematic position of this micro-organism could not be better defined than by the new genus *Vibriothrix* created by Castellani.

A BRIEF NOTE ON THE BIOCHEMICAL REACTIONS OF CERTAIN FUNGI, VIZ., *MONILIA KRUSEI*, *M. MACEDONIENSIS*, and *M. TROPICALIS*.

By ERIC C. SPAAR, M.D., B.S., B.A.Lond., M.R.C.P.

Physician, General Hospital, Colombo, and Lecturer on Clinical Medicine at the Ceylon Medical College.

(From the Ross Institute for Tropical Diseases, Putney, London.)

IT has been stated by certain authorities that the monilias have no permanent biochemical characters. I thought it might be of interest, therefore, to make an independent investigation into those of certain species of monilia the strains of which have been subcultured for quite a number of years.

The monilias I have investigated are the following: *Monilia krusei*, *M. macedoniensis*, *M. tropicalis*. These were isolated in Ceylon in the year 1910.

Besides litmus milk and gelatine, I passed the strains through the following sugars, namely, glucose, lævulose, maltose, galactose, saccharose, lactose, mannite, glycerine, inulin, dulcite, isodulcite, inosite, adonite, arabinose, amygdalin, salicine, sorbite, raffinose, dextrin, erythrite.

As regards litmus milk, the only change produced was a little acidity by *M. macedoniensis* after some days. No clot was formed by any of the monilia used.

There was no liquefaction of the gelatine in a single instance. The reactions in the sugars are shown below. No reactions other than those indicated occurred in any other of the sugar media, with the exception that *M. macedoniensis* produced slight acidity in raffinose without any gas formation.

The production of gas was constant, and the selection of certain media in this respect by the different fungi makes their differentiation in this way easy and accurate.

	M. krusei	*M. macedoniensis*	*M. tropicalis*
Glucose	AG	AG	AG
Lævulose	AG	AG	AG
Maltose	—	—	AG
Galactose	—	AG	AG
Saccharose	—	AG	AG
Lactose	—	—	—
Mannite	—	—	—
Glycerine	—	—	—
Inulin	—	AG	—
Dulcite	—	—	—
Isodulcite	—	—	—
Inosite	—	—	—
Adonite	—	—	—
Arabinose	—	—	—
Amygdalin	—	—	—
Salicine	—	—	—
Sorbite	—	—	—
Raffinose	—	—	—
Dextrin	—	—	—
Erythrite	—	—	—

In each case the reactions appeared in 24 hours and was markedly definite in 48 hours. The reaction in inulin, however, which was produced by *M. macedoniensis*, did not appear before the lapse of 72 hours and so also those in maltose and galactose by *M. tropicalis*.

The most interesting fact that has emerged from this research is that, although through all these years the growths have been kept renewed by subcultures, they have retained their original characters and have in no way deteriorated, while the results speak for themselves of the absolute dissimilarity in the reactions obtained.

I may mention that the biochemical characters revealed by my investigation are identical with those described by Castellani.

My best thanks are due to the Director of Tropical Diseases of the Ross Institute for permission to publish these notes.

FURTHER REPORT ON ACQUIRED IMMUNITY TO MALARIAL INOCULATION.

By J. Ernest Nicole, L.M.S.S.A.Lond.
Senior Assistant Medical Officer, Lancashire County Mental Hospital, Winwick.
AND
John P. Steel, M.B., Ch.B.Edin.
Assistant Medical Officer to the Hospital.

In the *Journal of Tropical Medicine* for December 1 last we reported 15 cases of general paralytics who showed a definite resistance to reinoculation with malarial blood, and mentioned that we had not had an opportunity of testing their resistance to inoculation by the bites of infected mosquitoes.

Since that date Colonel S. P. James, of the Ministry of Health, has been kind enough to help us in that matter. On November 21, 1925, three cases, which had previously proved refractory to repeated inoculations with malarial blood, were bitten by infected mosquitoes. The following is a brief summary of the results and of the previous inoculation history:—

Case 43.—Inoculated intravenously 27/7/24. Nine rigors resulted, terminated by quinine. Subsequently had relapses of malaria.

Unsuccessfully reinoculated:—

I.M.	...	..	February 11, 1925
I.V. ...	...	...	May 30, 1925
I.V. ...	...	...	July 27, 1925
I.M. ...	...	...	August 5, 1925.

Was subjected to mosquito infection on 21/11/25, and after 21 days' incubation period he developed true malarial pyrexia, with parasites in the peripheral blood.

He had six rigors, occurring daily, and terminating spontaneously, the blood becoming negative to the microscope before the exhibition of quinine.

Case 62.—Inoculated intravenously 29/4/24. Ten rigors resulted, terminated by quinine. No subsequent relapses.

Unsuccessfully reinoculated:—

I.M.	...	...	August 5, 1925
I.M.	...	...	August 31, 1925

Was subjected to mosquito infection on 21/11/25, and after 18 days' incubation period he developed true malarial pyrexia with parasites in the peripheral blood.

He had five rigors, occurring daily, and terminating spontaneously, the blood becoming negative to the microscope before the exhibition of quinine.

Case 51.—This case was treated by mosquito infection before admission to this hospital, and had a number of malarial rigors, details of which are unknown, although he acted as donor of infected blood to many other hospitals.

Unsuccessfully reinoculated:—

Mosquito	...	...	January 7, 1924
I.M.	...	...	April 30, 1925
I.V. ...	...	...	July 17, 1925

Was subjected to mosquito infection on 21/11/25. No pyrexia developed, but on several occasions from the 23rd to the 31st day after infection malaria parasites were found to be present very scantily in his blood.

The last case, No. 51, presents features of interest as he was successfully infected by mosquitoes originally. Since then he has been subjected to malarial infection by all three usual routes and has not shown pyrexia. Blood examinations have been made daily since December 1, and the results have been:—

December 1 to 13	...	...	Negative
December 14	...	...	One parasite found
December 15	...	...	One parasite found
December 16 to 19	...	...	Negative
December 20	...	...	One parasite found
December 21	...	...	Negative
December 22	...	...	One parasite found
December 23 to January 13	...		Negative

No constitutional symptoms of malaria have been observed, and since December 22, despite injections of adrenalin and milk, the patient has shown a consistently negative blood-picture.

In reporting these three cases, two of which have been successfully treated by mosquito infection after being resistant to inoculation with a known old-standing strain which had been eminently satisfactory to us for primary infection, we would like to mention three other cases.

Case 8.—This patient was resistant to reinoculation from our own strain on 27/7/25, but on 17/12/25 he was inoculated intravenously from case 62 (quoted above), who was rigoring as the result of direct mosquito infection. He had five rigors, occurring daily, after an incubation of ten days. His fever ceased spontaneously.

Case 40.—This patient was subject to reinoculations from our own strains on 17/7/25, and again on 6/12/25, but on 29/12/25 he was inoculated intravenously from case 8 (quoted above). After an incubation period of ten days he developed true malarial pyrexia, and is at present having rigors daily.

Case 79.—This patient was resistant to reinoculations from our own strains on 11/2/25, and again on 6/12/25, but on 29/12/25 he was inoculated intravenously from case 8 (quoted above). After an incubation period of ten days he developed true malarial pyrexia, and is at present having rigors daily.

It is possibly worthy of note that each of the successful cases mentioned, two from direct mosquito infection, one from the same strain but with one intervening host, and two after two intervening hosts, have in common the facts that they have been successful after prolonged resistance, and that daily rigors have occurred; in the three cases in which the malaria has terminated, a spontaneous disappearance of the parasites was observed.

We have again to thank our Medical Superintendent for permission to publish Hospital cases, and to Colonel S. P. James we owe a debt of gratitude for his help.

The Value of Iron in Anæmia. An Experimental Study (Charles Spencer Williams, M.D., and Harold N. Ets, *Archives of Internal Medicine*, September 15, 1925).—Inorganic iron, whether given by mouth, subcutaneously, or intravenously, is absorbed and may be found especially in the liver and spleen, but it is not converted into hæmoglobin. Animals made anæmic by one or several large bleedings do not recover any more rapidly when inorganic iron is given in any of these ways. The efficiency of food iron is very pronounced and animals on a diet containing food iron only, recover very rapidly from hæmorrhages that remove an amount of iron greater than exists in the entire body outside the food. In the light of the experiments reported the administration of inorganic iron has no therapeutic value in anæmia.

Treatment of Malarial Fever (Major Alexander T. Cooper, *The Military Surgeon*, October, 1925).—Of the malarial fever cases occurring at Fort Benning during the past three years 90 per cent. were of the tertian type; 10 per cent. estivo-autumnal type, 11·6 per cent. of the tertian cases probably relapsed in from two months to one year. In at least half of these relapse cases the probability of a reinfection can be reasonably ruled out, as the relapse occurred during the winter months. Thirteen patients with tertian malaria received the Army routine plus treatment with injections of arsphenamine. One relapsed. Three cases relapsed who had, in addition to receiving the Army routine treatment, also received an additional one month's quinine medication. Forty-three per cent. of tertian cases gave a history of previous attacks of malaria; 68 per cent. of these stated that they had received previous quinine medication; 44 per cent. of tertian cases showed gametes in their blood. Two out of 10, or 20 per cent., of estivo-autumnal infections relapsed.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments**, either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, **which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

GIARDIASIS.[1]

NOTWITHSTANDING many recent contributions on this subject, there still exists a considerable amount of doubt as to the degree of pathogenicity, if any, attributable to *Giardia intestinalis*. This organism, discovered in 1859 by Lambl, often bears his name, and is considered by many to be a harmless intestinal parasite, though recent investigation indicates that it may manifest real pathogenicity. Many cases of an explosive diarrhœa were met with during the war in France and in the East in which no other cause than the presence of large numbers of active *Giardia intestinalis* could be found in the stools. It would thus appear that this organism, when present in large numbers in

[1] Lyon and Swalm: "Giardiasis: Its Frequency, Recognition, Treatment and Certain Clinical Factors," *Amer. Journ. of the Med. Sciences*, September, 1925.

the small intestine, can give rise to diarrhœa with bile-stained mucus. The patients are never acutely ill, complaining only of a feeling of abdominal discomfort in addition to the diarrhœa. There is no tenesmus, and the stools are generally fæcal and bile-stained, and contain flakes of mucus. Microscopically large numbers of active *Giardia* can be seen, sometimes along with scanty numbers of red blood-cells. These clinical and microscopic findings readily serve to distinguish this condition from bacillary dysentery.

Until recently giardiasis has usually been considered a parasitic infestation of tropical and sub-tropical regions only. More recent work, however, indicates its greatly increased prevalence in temperate climates.

Since the inception and wider application of duodenobiliary drainage as a diagnostic procedure, the incidence of recovery of the living vegetative forms has greatly increased, and the condition has thereby become correspondingly more frequently recognized, especially in temperate climates. Obviously this manifestation in temperate climates is a matter of considerable importance.

As regards the mode of dissemination of giardiasis there is much evidence that transmission is chiefly by the cysts of the parasite. These cysts are very resistant and may be eliminated for years by individuals who are quite free from symptoms and apparently cured. Grassi successfully inoculated himself by ingesting the cysts. As in typhoid, so in giardiasis, fungus, food and flies are the chief offenders. Various rodents have been suspected of spreading the disease, but no evidence has yet been produced to show that human infestation is referable to them. Air-borne dust containing cysts may settle on and contaminate foodstuffs, and thus serve as a means of dissemination. Lyon and Swalm consider that the likelihood of such methods of transmission is suggested by the fact that, in children particularly, several members of the family may become simultaneously infected. They also consider that it is possible that by air-borne routes the respiratory tract may be invaded, for *Giardia* cysts have been found in bronchiectatic secretions, and they report that three cases of Bartle's all had chronic bronchitis. The great increase in this infection noted during the world war among returning troops also leads them to the belief that direct contact with dejecta and generally unhygienic living conditions tend to spread the disease.

Lyon and Swalm also insist on the frequent clinical association in the adult of giardiasis with diseases of the gall and bladder, bile-ducts and duodenum. It is usually resistant to all forms of treatment, and it would appear that as yet no specific treatment has been developed. Owing to the frequency of relapses being observed, caution should be exercised in prematurely claiming an actual cure in giardiasis.

F. E. T.

Annotations.

Experimental Studies with a Spiral Organism found in a Wild Rat and identical with the Organism causing Rat-bite Fever (H. Mooser, M.D., *Journal of Experimental Medicine*, October 1, 1925).—The spiral organism isolated from a wild rat has proved identical with that from a human case of rat-bite fever in Mexico City. Rabbits can easily be infected with these organisms. The subcutaneous inoculation of them is followed after three to five days by a local œdema, induration and inflammation as a primary lesion. About eight days after the appearance of the primary lesion, œdematous swellings and inflammation appear on the head and genitals as secondary lesions. The organism can be transmitted from rabbit to rabbit by coitus. Protective antibodies are to be found in the blood of infected rabbits at a time when the local lesions are still active. The peculiar character of certain of the lesions is probably due to the escape of the antibodies from the blood-stream. The organism belongs to the genus *Treponema*.

A Group of Micro-organisms Transmitted Hereditarily in Ticks and Apparently Unassociated with Disease (E. V. Cowdry, *Journal of Experimental Medicine*, June 1, 1925).—Pleomorphic, bacterium-like, Gram-negative, intracellular micro-organisms which stained much less intensely with ordinary dyes than most bacteria, were found in sixteen species of ticks comprising examples of the Argasidæ and the Ixodidæ. In six of these species studied intensively slight differences in the micro-organisms were detected, sufficient to permit identification of the vectors by microscopic examination of the micro-organism alone. No evidence was seen of injury to the tissues of the arachnid hosts of the micro-organisms other than that incidental to mechanical distension of the cells containing them. The detection of the micro-organisms in the eggs of ten species, in the unfed larvæ of eight species, and at nearly related stages throughout the life cycle of three others, leads to the conclusion that they are transmitted hereditarily.

Current Literature.

THE KENYA MEDICAL JOURNAL.

November-December, 1925. Vol. 2, Nos. 8 and 9.

Venereal Diseases Measures in Uganda (G. J. Keane).—In order to control venereal diseases and the high infantile mortality rate in the native population of Uganda Protectorate, salvarsan substitutes are issued free to native patients who cannot afford to pay for treatment. For the guidance of medical officers and assistants there is a standard course of treatment. Although the cost of drugs is not small the greater expense lies in the arrangements of distribution of the drugs, such as hospital staff, general

equipment, and attendance of the sick. The best policy for securing attendance for treatment and for maintaining re-attendances is based upon the following considerations: (*a*) Sympathetic handling of patients, particularly by medical officers able to speak to them in their own language; (*b*) offering highly efficient treatment in as painless a form as possible; (*c*) offering well-equipped and well-organized in-patient accommodation for such patients as require it; (*d*) combination of venereal diseases treatment with that for general diseases, and avoidance of special venereal diseases hospitals.

The Natural Enemies of Rats: Their Possibilities in Plague Prevention (G. H. Goldfinch).—The natural enemies of the rat include mammals, birds, reptiles, and at least one insect. The most important of the mammals are jackals, tenneck foxes, serval cats, wild cats, genets, civets, and the mongoose family. The birds are secretary birds, giant hornbills, hawks and owls. The most important insect is the Siafu ant. These animals should be protected and even increased, as the harm they do is insignificant compared with the danger of rats as carriers of plague. Natives rarely, if ever, kill anything that does not actually interfere with themselves or their stock, but in the European areas there is an increasing number of ignorant people who will kill or shoot anything they see simply because it is there. Another important factor is the use of poison for the destruction of the larger carnivora, which causes the death of natives and the wholesale destruction of vultures. The poisoned bait should be put out at night and taken up in the morning. Another point for consideration is the importation of small carnivora from elsewhere, and the most suitable for this purpose are the Indian mongoose and the little owl.

Some Observations of Pellagra in Nyasaland (H. J. Shelley).—Pellagra was first recognized in Nyasaland by Stannus in 1910, and its presence was again reported by Milne-Tough in 1922. Observation of the pellagrins in the Central Prison Hospital, Zomba, and from cases occurring amongst the general population lead to the following conclusions: (1) That pellagra is not a disease confined solely to prisoners in Nyasaland, as was previously thought, but occurs with comparative frequency amongst the general population. (2) That pellagra is not a disease which is caused solely by diet; if it were the cases would be more numerous in the Central Prison, where all prisoners receive a similar diet both in quality and quantity. (3) That it would appear that pellagra is a disease due to toxic absorption producing certain changes in the nervous system, followed by neuritis of certain peripheral nerves. This neuritis produces trophic changes in the areas of the skin supplied by the affected nerves, with the result that the skin becomes dry and scaly from interference with its nutrition. These trophic lesions of the skin appear most marked on those parts of the body which are exposed to sunlight, but cases have been seen where the affected areas were situated on the scrotum and buttocks. The distribution of the dermatitis was absolutely symmetrical on both sides of the body. In many respects the disease resembles myxœdema. Thyroid gland, one grain daily, produced a rapid improvement in the pellagrins, even when the skin lesions were severe.

A Review of a Recent Epidemic of Bacillary Dysentery with Special Reference to a New Therapy (A. J. Boase).—The author reviews a series of 117 cases of bacillary dysentery that have been treated at the Mulago Hospital during the past six months; they represent cases that arose in the gaols of either Kampala or Luzira. The epidemic began towards the end of October and reached its height during the early part of December. The series is divided into two groups, i.e., "The Saline Group" and the "Castor Oil Group." The better results were obtained with the second method of treatment. Castor oil is not claimed to be a specific; it acts merely as a palliative. But if it is of use in reducing the death-rate and restoring the individual to his normal capacity, it is well worth a trial in the treatment of bacillary dysentery.

Note on the Trypanosomiasis Census of the Populations of the Miriu River, Central and South Kavirondo Districts, Nyanza Province (J. O. Beven).—The census was made for the purpose of ascertaining the incidence of trypanosomiasis in the most heavily infected area of the province. The Miriu forms the boundary between Central and South Kavirondo, and the population affected can be divided into three groups: two on the south bank and one on the north. On the south bank the incidence of disease is 53 per cent. in one group; the percentage of the other group is not given. On the north bank the incidence of disease was found to be 29·2 per cent. The incidence is very high among children under 16, owing to the fact that they spend the greater part of the day either actually on the river or in the adjacent bush. The number of cases admitted to hospital during the last year is over eighty. In a certain proportion trypanosomes were found in gland-smears; the formol-gel test was positive in all; the clinical evidence was quite conclusive in every case, and in no case did the result of treatment, either by "Bayer 205" or tryparsamide, fail to confirm the diagnosis. Careful inquiry has proved that trypanosomiasis never completely died out after the epidemic of 1909-1912.

The Provision of Hospital Accommodation with Particular Reference to Infectious Diseases (F. J. Carlyle Johnstone).—The author shows the necessity for increasing the expenditure on medical services, which would enable the activities of the Department throughout the Kenya Colony to be extended in many directions.

A point worthy of consideration is the desirability of providing accommodation for the treatment of infectious and communicable diseases in addition to ordinary medical and surgical cases in one general hospital. This would probably result in (*a*) considerable financial saving in the cost of hospital administration, (*b*) conservation of staff, and (*c*) more efficient treatment of the sick.

Notices.

THE WAR AGAINST MALARIA.

Sir Ronald Ross leaves for Ceylon per Bibby Line S.S. "Yorkshire."

One of the primary objects in the founding of the Ross Institute and Hospital for Tropical Diseases, Putney Heath, S.W. 15, was to create interest throughout the Empire in waging a relentless war against malaria. There is possible to-day no disease causing more suffering and financial loss than malaria. Over twenty-five years ago Sir Ronald Ross made the discovery of the carrier of this disease, and although the successful application of his discovery has rendered certain tropical areas comparative health resorts to what they were at one time, proportionately little progress has really been made throughout tropical and semi-tropical countries.

Sir Ronald Ross in addressing recently members of the Ceylon Association, proposed a scheme calling for the co-operation of all Plantation Companies, believing it should be possible, within a short time, to drive malaria right out of Ceylon.

In certain parts of Malaya, Southern India and Assam, groups of Plantation Companies are dealing effectively with malaria, but if Sir Ronald Ross's mission succeeds it will not be a question of small areas being cleansed but the whole country. It is his intention to group Plantation Companies geographically, and each group will be dealt with by a resident malarial expert, who will carry out malaria control measures according to the conditions peculiar to his particular group, and report from time to time to a Central Committee. Every facility will be given to individuals to combat the disease effectively.

Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S., is Director-in-Chief of the new Ross Institute and Hospital for Tropical Diseases, and it is hoped that his visit will create world-wide interest in the urgent necessity of dealing drastically with tropical diseases generally. This will be very beneficial to the Empire and will hasten its profitable development.

BUREAU OF HYGIENE AND TROPICAL DISEASES.

(Late Tropical Diseases Bureau).

By decision of the Honorary Managing Committee of the Tropical Diseases Bureau, and with the approval of the Secretary of State for the Colonies the Bureau's name has been changed to "Bureau of Hygiene and Tropical Diseases." The Bureau traces its history back to 1908 when as a result of the International Sleeping Sickness Conference of 1907 the Colonial Office founded the Sleeping Sickness Bureau, which for four years carried on its work of preparing and publishing the *Sleeping Sickness Bulletins* in a room put at its disposal by the Royal Society. Towards the end of this period it brought out also the *Kala Azar Bulletin* and in 1912 it outgrew its accommodation and moved to the Imperia Institute. Here its scope was widely increased an it became the Tropical Diseases Bureau, publishing i place of the journals named the *Tropical Disease Bulletin*, now in its twenty-third volume, and th *Tropical Veterinary Bulletin*, of which thirteen volume have appeared. In 1920 it again outgrew its quarter and removed to what was then the new building o the Seamen's Hospital Society at 23, Endsleig Gardens, where it occupies rooms put at its disposa by the new School of Hygiene and Tropical Medicin Last year the Managing Committee recognizing th advances made in the practice of preventive medicin and the increasing need of the tropical and othe colonies for recent information on all branches o hygiene, decided to replace the *Sanitation Supple ments* of the *Tropical Diseases Bulletin* by a monthl *Bulletin of Hygiene* planned to meet the needs of th Dominions as well as the Colonies. The new journa will make its appearance this week. Dr. J. F. G Haslam, recently Government Medical Officer Health of British Guiana, has replaced Colonel Alcock as Assistant Director, and is in editori charge of the new Bulletin. The Bureau's name now co-extensive with its activities.

January 25, 1926.

A Four-grate Front-Fed Brick Built Destruct Plant of the well-known Meldrum Simplex Standa type is ordered for the town of Woollahra, ne Sydney, and brings the number of Destructor Plan installed in Australia alone to nine—the others bei at Annandale, Marrickville, Toowoomba, Newtow Lithgow, North Sydney, Prahran, and St. Kilda.

New Preparations, Inventions, &c.

BISMUTH TREATMENT IN SYPHILIS.

During recent years the intramuscular injection of bismu salts has been widely employed in alternation with organ arsenic in the treatment of syphilis. Of the various for available it is thought that the salicylate is the mo advantageous, and Messrs. Parke, Davis and Co., now supp ampoules each containing 2 gr. of that salt suspended in pu olive oil to which is added 10 per cent. of camphor and creosote, which drugs tend to obviate pain or irritation at t site of an injection. In an average case the contents of o ampoule should be slowly injected deep into muscular tis twice a week.

Bismuth salicylate ampoules (P. D. & Co.) are supplied boxes containing 6 or 12 ampoules.

SULFOXYL SALVARSAN.

This preparation has recently been issued by Messrs. Meist Lucius and Bruning, of Hoechst, in a 5 per cent. solution rea for immediate use. Sulfoxyl Salvarsan is chiefly used in t treatment of tertiary syphilis, and is now being employed by number of hospitals and V.D. centres in this country.

"Isacen" granules brand diacetyl-dihydroxphenyl-isatin a new purgative. The salient advantages of "Isacen" a that it is non-toxic, acts in a very small dose and only in t colon, and that it is not absorbed but excreted unchanged

Original Communications.

THE SEARCH FOR A MORE EFFICIENT PROPHYLAXIS AGAINST TUBERCULOSIS.

By F. Cevey, M.D.
Privat-Docent Lausanne University.

Tuberculosis is one of the most prevalent causes of mortality amongst young people, being the cause of more than half the deaths which occur between 15 and 40 years of age [1].

I.

The formula $D = \frac{V}{R}$ (Disease = $\frac{\text{Virulence}}{\text{Resistance}}$), was used by Galli-Valerio to show the relation between the virulence of the microbe and the resistance of the infected organism. It is a prime necessity in prophylaxis to suppress, whenever possible, the numerator Virulence. On the other hand, the possibility remains of amplifying to such a degree the denominator Resistance, that the fraction ceases to have any further practical value, the arrest or failure of the disease thus manifesting itself.

In the fight against tuberculosis a series of measures has been successively proposed tending to destroy tubercular contagion, but, until now, it has given very few results. In spite of all elaborate theories, without our knowing how or why, in the majority of the cases Koch's bacillus succeeds in stealthily invading the organism and continues to defy all means of destruction.

Failing to exercise any direct efficient action against the virulence, attempts should be made to intensify the resistance to the maximum.

In view of the more or less rapid wasting in phthisical subjects it seemed indispensable, in order to preserve our population from tuberculosis, to appeal first to the general rules of hygiene and to aim at restoring in threatened individuals as great a resistance as possible. After the marked failure of drugs the vogue of bodily exercise came into use, which is quite as powerless by itself to annihilate tuberculosis.

In fact, what correlation is there between general resistance and tuberculosis? If we draw a diagram of mortality in general, at different ages, we obtain a fairly regular U curve (Diagram II) the branches of which corresponding with the extreme periods of life indicate for both periods a very high mortality. The curve falling sharply from birth to about the fifth year and maintaining from that age to about the forty-fifth year a minimum, rises abruptly afterwards and without interruption during old age.

This curve, established by the figures published by Ascher [3] for the year 1909 in Prussia, shows that the general resistance of the individual, imperfect in early childhood and in old age, attains its highest degree approximately between the fifth and forty-fifth year and suffices during this period to maintain the general mortality at a minimum.

If we establish, according to age [3], the curve of mortality from true pneumonia and that from pulmonary affections due neither to pneumonia nor tuberculosis, we obtain curves exactly parallel to that of mortality in general. Consequently, it is most surprising that for tuberculosis and for pulmonary tuberculosis we get an absolutely different curve, presenting from birth a decrease until about the fifth year, rising slowly at first and from the eighteenth year more and more rapidly, attaining the highest maximum shortly after the twenty-fifth year and remaining at that level until the forty-fifth year with very little variation. After a further rise the curve then falls considerably in extreme old age; this last decrease and the stagnation of the curve between 25 and 45 are most probably due to the treatment on a large scale of tuberculosis amongst the working class by the German National Health Insurance. For the years preceding its activity, the rise in the curve of mortality from tuberculosis, on the contrary, in adults continues at the former rate from the twenty-fifth year to extreme old age.

A first fundamental conclusion is evolved from this study of mortality: *A good general resistance of the individual does not by any means imply a good resistance against tuberculosis.* It is precisely in the years when the general resistance is best that we find the highest mortality from tuberculosis. It is towards correcting this lack of parallelism that the fight against tuberculosis must tend; one sees from the mean part of the curve at least, that before 1914 the Germans had partly succeeded in this task. The disparity which still exists between the two curves (from mortality in general and from tuberculosis) allows us to measure the social effort still to be effected.

When we shall have brought the curve of mortality from tuberculosis between the fifth and forty-fifth year parallel to the curve of mortality in general we shall have socially accomplished all the progress which may be reasonably expected in this sphere. Another consequence is that from the disparity of these curves we can estimate, according to age, how many individuals die each year from tuberculosis whom we could save if there was a better understood form of prophylaxis.

Not only the study of the table of mortality, but direct observation on the living confirms that the resistance to tuberculosis is not identical with the general resistance of the subject. That those races who exist in the Fuegia Islands [4] and in Southern Arabia [5] have remained free from tuberculosis proves this clearly. In these tribes of an astonishingly vigorous physique and among those leading a nomad life, who can stand any rough weather, the least tubercular contamination is inevitably and rapidly fatal.

It is the same with animals: the Hungarian oxen living in a savage state, and captured by the lasso never show symptoms of tuberculosis, which has been abundantly verified post mortem; but six months of stabling in company with domestic oxen,

not specially chosen, suffice, however, according to Ostertag [6], to make them all tuberculous. Thus life in the open air and absolute endurance to atmospheric conditions have not contributed in developing in these animals any trace whatever of resistance against tuberculosis.

An analogical instance, particularly conclusive, is given by the Swiss Army, which undergoes intense sportive training during the mobilization. One would expect to find a decrease in the number of manifest tuberculous cases during the ensuing years, but precisely the contrary is shown. In 1914 there were 107 soldiers incapacitated by tuberculosis in the Swiss Army, 688 in 1915, 790 in 1916, 1,244 in 1917 [7], and 2,168 in 1918!

If in European countries numbers of weak and poorly developed citizens are capable of astonishing resistance to the tubercular infection, which is certain to prove rapidly fatal to an Indian Onas, physically well trained, it points directly to the fact that in the former the increased resistance is already a specific phenomenon of immunity, showing a sort of previously weakened vaccination of the race which enjoys consequently a resistance which, with a very superior training in the open air and a life of exposure to the elements, it has been powerless to endow upon the aborigines of the Fuegia Islands.

Hence, *the resistance to tubercular infection is of a specific nature*, depending, like all biological phenomena, in a certain measure, on the general condition of the subject, but not identifying itself with it. On the contrary, an excellent general condition can exist without any resistance against tuberculosis.

It is incomprehensible that whilst nature itself shows us in immunization the sure way to preservation and cure, we still persist in trying to increase the resistance against tuberculosis in children and adolescents only by non-specific means, which alone cannot secure complete success.

"Prevention is better than cure" has been echoed and re-echoed, and the so-called prevention of tuberculosis was decreed. This is a very praiseworthy aim, but it must be clearly defined.

It is important to aim at preventing the infection in infancy by seeking to diminish all exposure to contagion, and to try by direct measures against the bacillus to check the actual general contamination, though there is considerable difficulty in such a task.

On the contrary, and here lies the error, if to secure prevention of tuberculosis in children one pretends to make them escape contamination from Koch's bacilli in recommending life in the open air, sun and air baths, open air schools, sports, &c., we formally contest that such a result can be realized.

Until recently physicians still recognized in children a certain number of signs and stigmata which were characteristic of a predisposition to tuberculosis.

However, and here is a new point, actual biological methods allow us to assert that in reality such a predisposition does not exist. By a more rigorous examination, one after the other the signs which were described can be proved either to be without any causal relation to tuberculosis and due, for example, to rickets, syphilis, &c., or are symptomatic of tubercular infection of which they indicate a rather slow and torpid evolution.

Thus the loss of appetite and strength, certain digestive troubles, anæmia, the stooping attitude, the loss of weight, flattening of the thoracic wall, premature ossification of the costal cartilages, prominence of the scapula, atrophy of certain groups of muscles, the fleeting or persistent flush of the cheeks, the acceleration of the pulse, the instability of the temperature are, considered in groups or altogether, not signs of a predisposition, but already symptoms of tubercular infection itself.

It is in the same way that certain characteristics of physiognomy should be interpreted, easier to recognize than to define, and the significance of which did not escape the sagacity of ancient authors; thus a particular brightness of the eye and of the hair, a certain fulness of the figure, complexion fresh and rosy, to cite only a few of these traits, completed the picture of the "tuberculous beauty."

On the contrary, having duly ascertained the absence of infection, nothing authorizes us to diagnose in the person considered a particular predisposition to tuberculosis. Numerous authors are even of opinion, and the statistics of orphanages sanction their saying, that children of tubercular parents, separated from them as a preventive measure and not yet infected by them, do not show later any particular predisposition toward tuberculous disease, and indeed contract it more rarely than their comrades with an unburdened heredity [8].

In consequence, when philanthropy exerts itself "to prevent" tuberculosis in its "protégés" it is dealing with two distinct groups: On the one hand those not yet infected by Koch's bacilli, but merely underfed or suffering from various affections need appropriate treatment. Since these children have remained unaffected by tuberculosis in such conditions, it is an error to describe as "preventive" the mode of life to which they will be subjected by their protectors. On the other hand, in the ever-increasing number of children infected by tuberculosis, with its stealthy evolution and tendency to generalization, it is not a question of preventing, but of curing it.

We are little advanced in the prevention of tuberculosis, and the reasons are evident. Aiming at prevention, philanthropists, when they temporarily assist children infected by tuberculosis, are already in reality unconsciously *treating* them. *At the moment when an energetic intervention would easily and definitely in most cases arrest the infection, the child, by regrettable error, benefits only by an absolutely insufficient and merely preliminary treatment, from which any definite result cannot be expected.*

Thus, as we remarked in a recent work [9], "the predisposed" is in reality already a patient

hom it is necessary to help without delay, and
t when, after months and years of useless fight-
g against the invading infection, the appearance
indubitable clinical signs of the disease portends
ss the struggle induced than definite defeat.

To preserve children infected by tuberculosis
om this extreme, and to spare them a sickly
ildhood and weakly adolescence, to secure them
certain cure and lead them to normal working
e, a change of air, some weeks of rest and abun-
nt feeding are not sufficient. To stimulate and
rect in their young organism the still waver-
g functions of defence, it is necessary to have
course to a *treatment* capable of intensifying these
eans by appropriate and methodical training, in
ch a manner as not only to hold the tubercular
fection in check, but definitely to arrest its course.
r *better prevention let us learn to cure.*

* * * *

To the habitual notion of prevention of the
bercular infection in children, too often impos-
ble to realize in a given time, we have to sub-
itute that of an energetic treatment, as early
possible. Let us briefly examine the programme
d its possibilities.

The increased resistance to tuberculosis appears
the race as in the individual, as a specific
henomenon of immunity. The treatment must
im at entirely constituting or more frequently
restoring this resistance, the denominator of the
fraction showing the declared conflict between the
thogenic agent and the organism. The equili-
rium which manifests itself by the arrest of the
fection having at last been obtained, it will be
cessary to ensure, if possible, its consolidation
d by intensifying the resistance still more con-
derably, to render it definite.

What better method in experimental pathology
an immunization in its diverse forms allows us
develop the defence so as not only to increase
tenfold, but even to make the organism sustain,
thout injury, doses of bacterial poisons a thousand
mes the fatal dose?

If by immunization medicine has been able to
lebrate such triumphs in other spheres, why
hould we persist in ignoring its advantages in the
ght against tubercular infection? Doubtless we
ve not yet at command an approved vaccination
y attenuated bacilli against it (reserve being made
ntil further time-control for Calmette's new
ethod of vaccination). Does it then follow that
here is at the moment, in this respect, no other
ay leading to success?

An experience of more than twenty years allows
s to certify that, by using derived products such
diverse tuberculines, bacillary emulsion, &c., it
possible, if all the proper precautions are taken,
nd if sufficiently large doses are given, to obtain
uch an increase of the resistance in more than
0 per cent. of the cases, and one can only explain
hese results as being due to active immunization.

Our affirmation does not concern only the so-called "pretubercular cases" in which the result is still more striking, but also the cases of tuberculosis still curable. In these latter we can observe, parallel with the progress of the treatment, the cessation of toxic phenomena, with improvement in the weight, temperature, pulse and blood-pressure, diminution and then disappearance of the cough, expectoration and bacilli, healing of tubercular lesions and wounds, return of strength, and of a state of health which allows the complete resumption of work. At the same time we find in the person who has been treated a series of modifications of the blood and of the serum reactions (precipitation, deviation of the complement, opsonic index, Arneth table, &c.), evidence of the real transformation of the organic defence, but of which on many points the definite significance still remains to be established.

In cases of advanced decay and destruction (except, if the possibility of preliminary local intervention such as artificial pneumothorax, thoracoplasty, &c., transforming the situation, can be considered) the immunisatory training would, of course, be out of the question.

That training aims at stimulating the production of antibodies, rendering the subject, little by little, immune to the toxic products of the bacilli more rapidly than the progress of the infection.

The result of treatment will clearly manifest itself only when the organism, in response to the immunizing stimulation exercised in healthy tissue, will produce antibodies in sufficient abundance, to neutralize, proportionately to their diffusion, the toxic products elaborated by the tubercular foci. The subject, until then, in a more or less chronic state of toxæmia, will find himself, after treatment, in a condition analogous to that of a pneumonic patient after the crisis. It is this equilibrium of the resistance still unstable in the beginning, which the ulterior treatment must consolidate and render definite.

The production of antibodies being proportionate to the quantity of antigen administered, one realizes the impossibility of obtaining sufficient antibodies by the administration of minute doses of antigen. It is consequently useless to linger, in the course of the treatment, over too small doses of tuberculin, which cannot lead to anything.

We always advise beginners, after a complete and serious study of the question, to start by treating slight cases of the disease. Having seen the results, little by little, the physician will have more and more confidence in the method, and gain further experience, which will allow him to undertake with success the more serious cases. He will also have acquired the necessary authority for the psychotherapeutic part of the treatment, always so important with the tubercular patients, too often capricious and easily discouraged.

II.

In the foregoing, we have shown the necessity of developing, as far as possible, in all the infected

subjects, by means of a sufficient immunisatory training, as strong a specific resistance as possible against tuberculosis, since a good general condition does not *ipso facto* indicate a resistance against the infection as sufficient as might have been expected.

From the fact that many individuals with an ailing appearance have for years shown a marked resistance to tuberculosis it would, nevertheless, be absurd to conclude, conversely, that resistance is without any correlation to the general condition. It is well known that after a certain degree of organic wasting no further particular resistance is manifested with regard to the infection, and then its more and more accelerated course henceforth advances irremediably.

In these circumstances, if it is legitimate to connect the simultaneous lowering of the general condition with the progress of the infection, it is natural to infer, during improvement in the course of treatment, a temporary abatement or even a real remission of the infection. It is thus very important to record the variation of the patient's condition of nutrition along with the direct clinical manifestations.

As regards this, we must proclaim as an important improvement the introduction by Pirquet [10] of a formula of general value, which characterizes rapidly, and with sufficient exactness the state of nutrition. The usual simple record of the weight is, indeed, only of value so long as the age, height and sex of the subject are considered. If we are dealing with a child, as a result of the increase in size that may have occurred, an increase in weight, in a given time, does not necessarily signify a corresponding amelioration in the state of nutrition.

If one wishes to compare the state of nutrition in different subjects, the unequal individual development of the legs also conduces to falsify the results, based merely upon measuring the height. One sees from this, considering the various elements in question, how complicated, in reality, such comparisons are and how easily they are rendered erroneous.

Relying on the former works of Henning, which establish that in man the length of the intestine is equal to about ten times the height (H) of the subject seated (measuring from the seat to the vertex) Pirquet shows that the intestinal surface itself corresponds to the square of this length (H^2). Extending his research, Pirquet also verifies that the cube of (H) is equal to ten times the weight of the body in grammes (P). Thus, the state of nutrition $N = \frac{\sqrt[3]{P}}{H}$; a formula to which, by the contraction of a Latin phrase defining it, the inventor has given the name of *pelidisi*.

According to Pirquet, the normal pelidisi of an adult is equal to 100, and in physiological limits may be raised to 105 in fat individuals, and fall to 95 in thin individuals. In the growing child, the pelidisi is a little lower. One may admit, in general, however, that a fall below 94·5 indicates a condition of under-nutrition ; when it reaches 92 and under, the American Mission d Help, which has applied this formula on a larg scale, considers that the under-nutrition thus re vealed is an indication that a supplementary gran for nourishment should be made.

The value limit of 94·5 having been definitel confirmed by the repeated examination of mor than 150,000 children, it is not necessary to insis on the considerable practical importance of th pelidisi for the rapid and sufficient determinatio of the state of nutrition.

Citing a personal instance, I will indicate th comparison of the state of nutrition in two youn girls, aged 8 and 9 years respectively, and of th same height, measuring 133 cm., the first weighin 30·3 kg., the second 28·6 kg. Do they both show good state of nutrition, and in which is it mor accentuated? The calculation of the pelidi allows us to determine these questions easily an without ambiguity.

The first little girl measuring, when seate 72 cm., the second only 68 cm. (H value), th result is that the latter has a pelidisi = 96· absolutely satisfactory for a child, whilst her litt companion, who has a more favourable appearanc if one judges in the usual way, having the sam height, but being heavier by 1·7 kg. presents reality a pelidisi of only 93·3, which shows u deniable under-nutrition, unsuspected till then.

Pirquet cites, on the other hand, the followi instance: the weight of a nursling has passed f tween the third and sixteenth week from 3·7 k to 5·25 kg., increasing thus by 42 per cent. Durin this time the pelidisi has, nevertheless, remaine unchanged — 94, the value of H having passe from 35 to 40 cm.

Inversely, the investigation of the pelidisi allow one to calculate the optimum weight for eac child. One thus sees the usefulness of the i vestigation of the pelidisi chiefly for the children specialist, and the resulting advantage for the ear diagnosis of under-nutrition.

* * * *

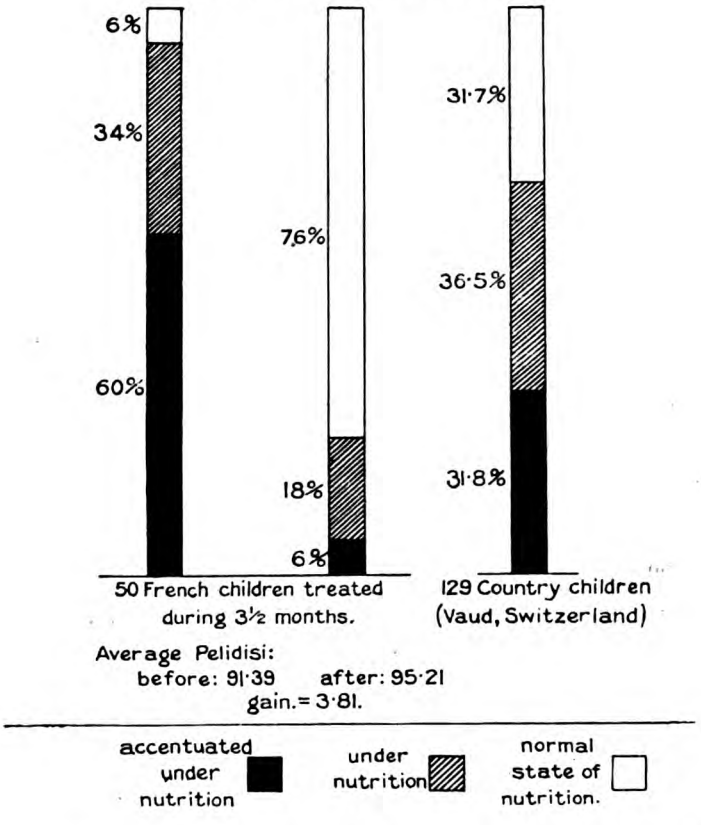
Asked by the committee of the Society "Sa feu ni lieu" to treat in the "Pavillon Bourget at Croisettes s/Lausanne, fifty little French ch dren from the devastated areas, all infected tuberculosis, and of whom about twenty show the usual local glands, as well as light pleural pulmonary symptoms, it seemed interesting to stu the variations of the pelidisi in the course of thr and a half months of immunisatory training which we subjected them. Without exception, t children have all increased in weight in the cou of the treatment, from 0·8 to 8·1 kg., the increa on an average being more than 3·3 kg.

Diagram I indicates the variations of the pelid in these children. It shows that on their arri only 6 per cent. of the children were in a w nourished condition, 34 per cent. were und nourished, and in 60 per cent. the under-nutrit was still more marked. After three and a h months' treatment, one could record that for 6

cent. of the children the respective gain in weight had been 2·200 to 2·900 kg., but, nevertheless, not sufficient to compensate their marked under-nutrition. In 18 per cent. of them who had gained from 1·900 to 5 kg., simple under-nutrition was still present, and in 76 per cent. an absolutely normal state of nutrition was found.

These results may be considered, without exaggeration, as entirely satisfactory; it is interesting to compare them, *si parva licet* . . . . with those obtained in Austria in 1920, by the American Mission of Help.

A first study of the pelidisi in the Austrian children showed that nutrition was more defective in Vienna [11-12] (average pelidisi = 91·6) than in certain towns of lower Austria, where it was found necessary to distribute food (average pelidisi = 89·04), and slightly better in the remaining towns where this distribution was withheld (average pelidisi = 93·68).



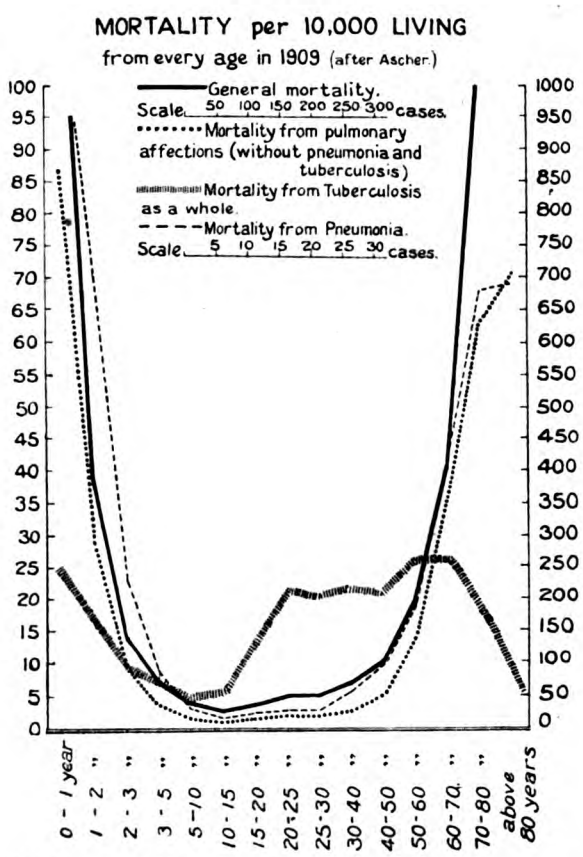
After six to nine months' assistance, including up to 400,000 meals per day, on a fresh examination of the children it was found that in Vienna the average amelioration of the pelidisi was 0·90, and in the assisted children in the towns of lower Austria 0·35, whilst in the unassisted children of the other towns the average pelidisi had, on the contrary, fallen during the period considered by the same amount of 0·35.

In the French children infected by tuberculosis the state of nutrition on their arrival was worse than in the children of Vienna, the average pelidisi not being more than 91·39. Considering the limited resources, they were given very simple but sufficient food, and treatment by tuberculin was carefully individualized, enabling them to support without reaction and in perfect condition varying doses reaching, after three and a half months, in a number of them, a final dose exceeding half a gramme of Koch's old tuberculin.

Under these conditions, *the average pelidisi of the children treated had risen* 3·81 (*i.e. to* 95·21), thus *showing, in a period of two or three times shorter, an increase fourfold that obtained by the American Society of Help* in Vienna by the sole use of supplementary food. It seems difficult to illustrate better the advantages of this specific training of the resistance the importance of which, for getting rid of tuberculosis, we have shown previously.

DIAGRAM I.

CHANGES IN THE STATE OF NUTRITION.



* * * *

To appreciate the entire value of the above result, with the fifty protégés of " Sans feu ni lieu," it was still necessary to compare their state of

nutrition at the end of the treatment with that of Swiss children, living in the country, with regard to whom no statistics had been previously established.

For that purpose we have examined six classes of children (129), representing almost the entire infant population of two prosperous villages taken at random, in no way different from the neighbouring villages, not having any factory and being entirely devoted to farming. The results of our investigation have proved most disappointing. (See Diagram I.) We found a good state of nutrition only in 31·7 per cent. of the children, under-nutri-

DIAGRAM II.

The scale figures on the left of the chart represent the mortality from specific complaints; the figures on the right represent the general mortality scale (the heavy line).

tion in 36·5 per cent. and accentuated under-nutrition in 31·8 per cent.

A definite conclusion may be drawn from these facts: On their arrival in Switzerland, the fifty French children were suffering from under-nutrition and tubercular infection: considered only as "predisposed" they would simply have been lodged in the country like their companions of the holiday-camps. Under these conditions, even in prolonging their stay indefinitely, one could not reasonably hope to see them surpass, as regards their state of nutrition, the country children with whom they would have been kept. In other words, instead of finding, as on their arrival, a good state of nutrition in only 6 per cent. of the children, one could have found it on their departure at the most in 31·7 per cent. of them as among the peasant children of the country.

In reality, in addition to simple but sufficient nourishment, the children were given an accelerated treatment for their tuberculous infection; after three and a half months, 76 per cent. of them showed a good state of nutrition. It is, therefore, no exaggeration to attribute this considerable increase in the percentage of the children, with normal pelidisi, to the special treatment that was granted them.

In short, in not only correcting the under-nourishment, but, *by treating at the same time the accompanying tubercular infection, the gain realized as to nutrition has been more than doubled.* (76 per cent. compared with 31·7 per cent.)

* * * *

Why do we encounter such defective nutrition in our country children? Must we blame a defective diet badly adapted to the child, although sufficiently abundant? Since by actively treating the children infected by tuberculosis, one finally arrives at the result that a normal state of nutrition is found among them, about two and a half times more frequently than amongst the peasant children of the district. Does this mean that in the infant population of our country districts, reputed as healthy, the tuberculous infection is much more widely spread than is generally thought, and is responsible for the existing state of malnutrition?

We may be well enough informed regarding the frequency of the tuberculous infection in children living in towns, and particularly in large towns, but we still lack positive information as to its prevalence in the country districts. It is indeed far from easy to obtain information regarding it. The peasants are apt to look with distrust on the intervention of the physician, and the simple reaction of Pirquet, however, inoffensive, cannot be practised without difficulty in series, except in hospitals.

Consequently we acknowledge the good sense and intelligent goodwill of our peasants. When advised of what we were asking, they immediately placed their children at our disposal, thus ensuring the prompt success of our inquiry. The results unfortunately, more than confirmed our apprehensions. In the youngest children (from 7 to 10 years) a positive Pirquet was present in 29·4 per cent. and in the older children (from 10 to 15 years) we found it in 61·1 per cent., i.e. twice more frequently.

As it is hardly possible that contamination in the family be greater after ten years of age than earlier, it is probably to the schools, until further information, that we must attribute this formidable increase of the infection between 10 and 15 years.

The objection may be made that our research refers to a limited number of children; we regret this very much. However, having examined, with

few exceptions, all the children attending the village school, in a district in no way conspicuous by its tubercular mortality, we doubt whether the result, if recorded elsewhere, would be essentially different.

Undoubtedly there is an important and extensive inquiry to be made, which only the Government can achieve satisfactorily. The elementary school being obligatory in our country, we have the right to exact that full guarantee be given that children cannot contract tuberculosis there.

We can now elucidate a last point of our study, namely, whether the established bad state of nutrition of our country children is due to an unsuitable diet, or, is not, as we presumed, the direct consequence of tubercular infection, hindering the child from thriving.

If the latter hypothesis be correct, we must find the average pelidisi in the uninfected children normal and the contrary in the others. In fact, we observed in the children from 10 to 15 years with a negative Pirquet an average pelidisi of 94·56, indicating a good state of nutrition, while the mean pelidisi in the group with a positive Pirquet had not exceeded 93·47, indicating a characterized state of under-nutrition. Since we have no reason to think that the food was different for these two groups of children, or that one of them had received unsuitable food, it follows *that the under-nutrition observed is in direct correlation with the extent of the tubercular infection.*

* * * *

Thus we find in the country, as well as in the cities, a considerable tubercular infection in children, undermining their vitality. Later they become patients, but before joining the ranks of those who die as a rule between 15 and 40, they will not fail to infect new generations of children, thus ensuring the perennity of the vicious circle. What remedy is there?

First, we must not wait to fight the infection until it has become a disease, difficult to cure and dangerous to others. We must, on the contrary, look for it in its earliest stages, by the systematic examination of the children at school (clinical symptoms, pelidisi, X-rays and Pirquet's reaction). At the first sign of under-nutrition and diminished resistance, we must immediately intervene with an energetic treatment, in which immunisatory training must *precede* physical training. Later on it will be necessary to examine periodically the cases dealt with, in order to treat them again in good time, if necessary. Simultaneously, one must prevent, as far as possible, the spread of infection (education and instruction of the people, especially of the patients, obligatory disinfection of each apartment on every change of tenants), &c.

Such a programme can succeed only with the help and active participation of the Government and that of physicians who must be carefully trained for this special task and, to be fair, receive a satisfactory remuneration for it.

Whatever diverging opinions there may now be, regarding both the respective value of the proposed treatment and that of the physical training to which philanthropists endeavour to subject the children, it is quite evident that all physical training would be considerably facilitated if, by a previous immunisatory training, three-quarters, instead of one-third, of those subjected to it, presented, from the beginning, a satisfactory state of nutrition. At any rate, it will be agreed that a method which is capable in three or four months of providing for tubercle-infected children a satisfactory state of nutrition in a percentage two and a half times greater than that encountered among children enjoying country life all the year round, deserves the attention of hygienists and physicians.

A CONTRIBUTION TO THE STUDY OF THE PATHOGENESIS AND TREATMENT OF SEA-SICKNESS.

By ROMOLO RIBOLLA, M.D.
Physician in the Italian Mercantile Marine.

SEA-SICKNESS owes its origin historically to the same epoch as navigation itself. It is only seldom that among those who take a sea voyage for the first time there are not some who pay tribute to the disturbance of sea-sickness; but in general only until habit has accustomed them to the ill-effects of the sea. There exist, however, special conditions of the movements of ships which produce this malady even in the oldest and most experienced navigators, whilst there are some who, in spite of habituation, never succeed in conquering their special predisposition, and amongst such are not to be missed as examples the names of great admirals, such as Nelson, Tegethoff and others, who continued to suffer from sea-sickness on the slightest movement of the ship. Towards the middle of the modern epoch, when navigation commenced to assume vast proportions, authors began to concern themselves with this disease, and to-day there exist no less than 300 synthetic reviews on sea-sickness, but of all the theories which have been evolved to explain its pathogenesis none have with-

stood the rigours of criticism, so that therapy still remains inefficient.

I.—Ætiology.

The principal cause of the manifestations and the disturbances in sea-sickness is given as the movements of the ship, movements that aggravate the syndrome in proportion to their variety and violence.

It is well known that the principal movements which the waves impress on a ship are two: (1) Rolling (movements in the longitudinal axis); (2) pitching (movements in the transverse axis). Pitching causes greater suffering than rolling. There exist also disordered movements which impose the most varied oscillations on the ship on which I have laid some little stress, and which do not permit of complete well-being even in those who have long been habituated to navigation, except those who are endowed with absolute refractoriness.

More than a malady, sea-sickness is a functional disorder which sometimes presents characters of real gravity, from simple oppression or slight nausea to persistent and intractable vomiting accompanied by phenomena of suffering generally irrepressible and producing a really painful symptomatic picture. Women are generally more susceptible to sea-sickness than men, and this is easily explained when account is taken of their sensibility, excitability, and gracile constitution, which account for their greater predisposition.

Regarding age, it is ascertained that children and old people are more rarely subject to it, from which observation has sprung perhaps the most ancient opinion thereon, first expressed and upheld by Plutarch, and then in times not remote by Guepratte, that sea-sickness was for the most part due to impressions and to fear; Guepratte also supported this hypothesis, averring that he had observed that children, like animals, became similarly immune to it. However, I can affirm that he had not made a very precise observation, since what had in effect been seen by many others had escaped him, and that is that children, even more rarely than adults, for a reason which I shall more closely deal with, are similarly affected by sea-sickness, and that not even dogs, monkeys and horses are exempt from all the very grave disturbances which the movements of the ship cause.

II.—Predisposing Causes.

Poor digestion and overfilling of the stomach, as well as absolute fasting, are causes predisposing to sea-sickness. Other predisposing causes are disgusting sensations such as a penetrating stench, vitiated air, the smell of the kitchen, the sight of persons vomiting, &c.

III.—Symptomatology.

Sea-sickness begins with a sense of general malaise and heaviness of the head, a state of abulia and vertigo. On this first disturbance there follows often with great precipitancy severe nausea, accompanied by salient vasomotor phenomena; the face becomes very pallid, the extremities cold and cyanotic, and the respiration embarrassed. All these phenomena reach a culminating point when vomiting ensues, aft which a slight but false relief of suffering follow with another brusque movement of the ship, howev all the symptoms return in aggravated form and t patient then presents a syndrome of real gravi Sea-sickness subsides at once on the cessation of t cause and it rarely leaves any sequelæ. No fa cases can be attributed to it.

IV.—Pathogenesis.

Much—indeed too much—has been written on t pathogenesis of sea-sickness and many and varic are the theories which have been enunciated a upheld. Without detailing the history and criticis of these hypotheses, I limit myself to a sim enumeration:—

(1) Theory based on the influence of fear on t psyche. This theory was held by Plutarch, and m recently by Guepratte, but has no serious foundati

(2) Theory of the miasmatic or microbic ca (Semanas), not now held by anyone.

(3) Theory of diminished force of the blood in t arteries (Pellerin and Fischer)—opposed to the the of Wollastone—has not withstood the simpl criticism.

(4) Theory of the congestion of a special segment the nerve centres and of the spinal medulla; not ev the author justified this hypothesis experimentally.

(5) Theory of repeated cerebral commotion; fi held by Fopsagewiss and later by Lusey and Janowl a theory also easily destroyed.

(6) Theory of the ennervation of the cephalo-rac dian fluid, held by Antric in his "Theorie phisiologiq du mal de mer." This one-sided theory was also eas destroyed by valid arguments.

(7) Theory of otic vertigo, enunciated by Erasm Darwin and developed by Arronsohne, Orsian, Bonn Hewitt and Wilson Fox; a theory which at first h a certain amount of support, but has lately be abandoned.

(8) Theory of muscular effort necessary for t maintenance of equilibrum (de Rochas); easily co bated by the fact that complete relaxation of all t muscles by assuming the horizontal posture do not abolish the symptoms.

(9) Theory of the perturbation of the static cent (semicircular canals, cerebellum). In recent tim much attention has been paid to the condition of t circulation in general, and that of the organs particular. Bedart was the first to connect sea-sic ness with a variation in the direction of gravit According to the author visual vertigo does not appe capable of producing those variations to which mari vertigo is due. This hypothesis, recognized as being some importance, did not explain how the variatio in the direction of gravity could act on the ampul and the semicircular canals, which, according Reynold, Darnall, Massini, Barnett, &c. should pl the salient part in the pathogenesis of this malad especially as Bedart affirmed that deaf-mutes we immune from sea-sickness.

(10) Psycho-somatic theory of Rosenbach. He he that the pathological state in sea-sickness consists

local anomaly of the functions of those organs which are most susceptible to tossing movements without the intervention of the nervous system, the action of which would be secondary.

(11) Theory of the repeated difference of pressure between the liquids and solids of the organism (Letlener and Fischl).

(12) Theory of diminished respiratory exchange (Dubois).

(13) Theory of nervous and muscular exhaustion and hyperexcitability of the centre of equilibrium (Schwerdt).

(14) Theory of the circulatory modification of the brain (Bing).

(15) Reflex theory (Haegen-Torn).

(16) Theory of the agitation of the abdominal viscera and splenic hyperæmia (Dutremblay, Kerandsen, Calliano, Rotondi).

Amid so many discordant opinions it is difficult to obtain a definite concept on the genesis of sea-sickness, many having accepted an eclecticism which somewhat cloaks our ignorance of the phenomenon.

Doubtless other things than movements of the ship which constitute the prime cause of sea-sickness, are capable of favouring and augmenting it, such as the atmospheric conditions, direction of the wind, the temperature of the surroundings, the smell of tar, of cooking and of smoke, dietetic errors, the intestinal functions, mental sufferings, abnormal nervous excitability, &c. Eliminating, however, the concomitant and predisposing causes, we come to consider the pathogenesis of the disorder, endeavouring among so many theories to arrive at that which is in harmony with experimental data, and with symptoms presented by every sufferer, and with criteria *ex juvantibus*, and which can be accepted as the most logical and most responsive to the control of research.

The theories which most fulfil these conditions appear to be:—

(1) The theory of Darnall, Massini, and Barnett, that of perturbation of the static centre.

(2) The theory of Dutremblay, Calliano, Rotondi, that of agitation of the abdominal viscera.

(3) The theory of Nolf (upheld also by others), that of vertigo from excitation of the vestibular nerve by hyperæmia of the semicircular canals producing irritation of the vagus.

The first is undoubtedly the most important, as in sea-sickness circulatory disturbances are well-marked. All explanations, however, fail to determine the nature and grade of the modifications of the encephalic circulation in its relation as cause and effect of the altered functions of the other organs.

The second, that is, concussion of the abdominal organs and consecutive irritation of the ganglia and flexures corresponding to them (Kerandsen, Dutremblay, Calliano), was held in great consideration, so much the more that the critera *ex juvantibus* when tested mechanically and therapeutically appeared to give positive results.

I consider that the results obtained were due to an action which combated some of the symptoms but not the cause, against which we ought to concentrate our forces, and not merely against phenomena which are the consequences of it. Again, therapeutic criteria demonstrate that vasodilators (amyl nitrite) and mechanical means (compression of the cœliac plexus) give results of little or no account. The slight relief from bromides has slightly diminished the suffering from sea-sickness, acting as they do in all cases of suffering and pain by their calming action on the whole organism.

Recently a gastro-suprarenal theory has been enunciated, but I attach little importance to it. It is also necessary to study diligently the mechanism of action of the symptomatological movement *ab origine*, and then to ascertain the precise therapeutic measures to counteract it. Nolf's theory is undoubtedly the most acceptable, being the most logical and complete.

V.—Personal Researches.

These were made during voyages from Genoa to Rio de Janeiro and to New York and in the Mediterranean, under the guidance of Professor E. Bertarelli. I experimented with a complex remedy, named "zoe," which produces ischæmia of the ear with an elective calming action on the pneumogastric. It comprises two liquids, one of which is applied as a tampon soaked with it to the external auditory meatus, and the other is taken as drops, and its effect is immediate and lasts for seven hours.

Rather than enumerate the successes of these experiences I prefer to describe proved and interesting cases. Above all, I can with confidence affirm that in all those cases in which instead of sea-sickness disturbances from slight movements occur, tampons on the ear alone have caused disappearance of the premonitory state of malaise and nausea which preludes sea-sickness proper. In most other cases the drops of the preparation have excited an almost immediate sedative action. Here are two cases which appear to be of special interest:—

(1) On the steamer "Tocra" between Civitavecchia and Terranova, the traveller R., before embarking took fifty drops of the preparation. The sea was high and the departure of the vessel was delayed by the difficulty in leaving port. The patient had affirmed explicitly that he was extremely sensitive to sea-sickness, which in him was comparatively violent from the slightest movement. On leaving port the patient was able to walk about, to smoke, and to eat, retiring to his cabin at eleven o'clock to sleep. Next morning he awoke in good condition and commenced to rise to perform the usual toilet, but had scarcely assumed the erect posture when he was suddenly seized with vertigo and vomiting. He then lay down and took another twenty-five drops of the medicament; in eight minutes he was able to return to the deck, where he remained walking and talking to the end of the voyage.

(2) Signora M. C., a very sensitive subject to sea-sickness, had wished to take a voyage to Capri, relying on the calmness of the Parthenopian Gulf, but was about to disembark at Sorrento, a prey to the gravest disturbances. The husband, somewhat more

resistant, had also suffered severely. Supplied with the medicament they were persuaded to continue the voyage, which they then completed without any further disturbance. It is unnecessary to relate further cases, all equally successful. In all I encountered a toxic excitation of the vagus during the sea-sickness.

The Theory of Nolf.—Dr. P. Nolf, Professor in the University of Liege, published an original memoir on sea-sickness in 1921. He confirmed the already ancient opinion of the vertiginous origin of sea-sickness, adding newly-acquired information on labyrinthine vertigo. The essential organ of equilibrium is situated in the internal ear and consists of the three semicircular canals arranged in three planes and containing lymph affected by movements of the head. These movements of the head affect the extremities of the vestibular nerves, so that normally the vestibular apparatus constitutes the principal organ of the sense of equilibrium.

Excitation of the vestibular nerve in man provokes oscillatory movements of the ocular globe known as nystagmus, with a sense of loss of equilibrium and vertigo. According to Nolf, this vertiginous expression exists in sea-sickness, but does not constitute its essential character. The vertigo, if sufficiently intense, is accompanied by a sensation of malaise, cold sweats, salivation, cardiac palpitation, facial pallor, sense of prostration, nausea, vomiting and diarrhœa. This is precisely the syndrome observed in sensitive subjects after excitation of the vestibular nerves, either by a simple injection of cold or warm water into the external auditory meatus by the voltaic current, after simply turning in a revolving chair or in a game of carousel or see-saw.

These reactions are readily explained if one recalls that the vestibular nerves are in the immediate neighbourhood of the nerve roots and nuclei of origin of the salivary nerves and the nerves of vegetative life, the tenth pair (pneumogastric or vagus).

Equally by the laws of nervous irradiation, every irritation of the vestibular nerve should diffuse towards these nuclei and create a state of hyperexcitability of the nervous elements of which they are composed.

Excessive salivation results from excitation of the salivary nerves, and from excitation of the pneumogastric a complex of symptoms on the part of the heart and the digestive tube. This nerve furnishes moderating fibres to the cardiac muscle the excitation of which provokes, at its greatest, arrest of the heart, slighter diminution in the frequency and intensity of its contractions. Hyperexcitation of the vagus nerve, termed also vagotonia, tends to diminish the work of the heart, and consequently the velocity of circulating blood. It also explains the state of malaise and of more or less profound depression of strength, with a tendency to syncope.

In comparison with the cardiac fibres of the pneumogastric the filaments of this nerve, which supply the digestive tube, are excited by the mobility of this organ, so that the hypertonia of the vagus creates a condition of generalized spasm or of contraction of the digestive apparatus. This retards the passage of stomach contents towards the intestine, establishing a spasm of the pylorus. This results sooner or later in drainage to this organ, as shown by vomiting, the inevitable consequence of spasm of the pylorus.

Sea-sickness, even in the most sensitive persons, is not produced instantaneously; it is due to abnormal excitation of the vestibular apparatus by incessant changes, and rarely to the position of the body on the ship in movement; it is augmented by the view of the movement of the ship or its contents, of the waves, and probably also by the disharmony between the motor reaction which results from vestibular excitation, and the forces, more or less deranged, of equilibrium.

To sum up, in its essential elements, sea-sickness, according to Nolf, is a reflex, and, like all reflexes, comprises an afferent or centripetal path towards the central nervous system, a centre, and an efferent or centrifugal path. The centripetal path is the vestibular nerve, the centre is constituted by the fibres of origin of the cranial nerves, which preside over the functions of the heart and digestive tube and its annexes. The centrifugal paths are distributed in the cranial nerves, and particularly in the pneumogastric. Hence the final result of the reflex is an exaggeration of the activity of the pneumogastric nerve, constituting the state of *vagotonus*. Since Nolf's theory was first expounded the new knowledge of the vestibular physiopathology and the study of labyrinthine excitation have thrown a new light on the ætiological discussion of sea-sickness.

It is also now known that a syndrome quite similar to that of sea-sickness in labyrinthics and in individuals seated in a revolving chair, the rapid revolutions of which produce movement of the endolymph in the semicircular canals. Further evidence is furnished by the fact that a warm or cold douche into the ear provokes abnormal movement in the endolymph of the canals and this determines real sea-sickness. Ruttin, at a time when the disturbance of the sea was suppressed, gave a bilateral warm douche: the sea-sickness immediately appeared and continued as long as the douche. Dragotti has recalled attention to the work of Jones, Bárány, and others that deaf mutes in whom the vestibular mechanism is imperfectly developed do not suffer from sea-sickness. Torcelli was one of the first to uphold this theory.

Before pursuing this question further, I consider it opportune to make some brief anatomo-physiological remarks on the semicircular canals. The three osseous semicircular canals, superior, posterior and external, take the form of tubes curved like arched hoops opening into the vestibule, and having an ampullary form near one end. The membranous semicircular canals occupy the interior of the osseous canals, and, although not completely filling them, present the same configuration.

The semicircular canals are filled with endolymph and perilymph, clear, colourless liquids, and in their ampullæ are calcium carbonate crystals (auditory powdered otoconia). In some fish these crystals constitute real stones (otoliths) of three to six centigrammes in weight and represent the auditory organ (V. Nuvoli, *Pidiologia del l'organo uditivo*, Loescher, 1907).

The large otoliths are evidently in relation to the surrounding water in which the fish live, and being supported by water on all sides, lose much of their weight. The otoconium in higher vertebrates comes into direct and immediate contact with the nerve terminals and, when sufficient, excites their sensibility, which is proved to be marvellously exquisite. Further, it cannot be denied, as Nuvoli affirms, that the microscopically crystalline constituents, the otoconia, being more mobile than a single large otolith can excite the nerve terminals in the macula more particularly corresponding to the least movement of the body, and represent a comparative progression of the single otolith.

I leave in this relation the word to Prof. G. Nuvoli, who has eviscerated all the vestibular physiopathology in a recent publication. Above all, he absolutely denies, and in this is in perfect accord with Cron, the hypothesis of Goltz, according to which the disturbances of the endolymph contained in the semicircular canals which depend on the movements of the head in this way provide adequate physiological excitation of the ampullary nerve terminals. On the one side is the capillarity of the membranous canals, and on the other is the density of the endolymphatic fluid which rather resembles mucus. Considering that the osseous canals which, in higher vertebrates contain the membranous canals, in fish are sometimes reduced to simple hooks (gami) which only enclose a small tract of the membranous canals, which thus remains almost free within the osseous capsule or cartilaginous labyrinth, whilst the hook serves exclusively to fix the direction of the canal.

If, then, in fish there is not produced adequate excitation of the ampulla, it naturally cannot be produced in the higher vertebrates. The endolymph merely represents the natural surroundings necessary for the life of the vestibular nerve terminations which were born and live exclusively in water, as above pointed out by Nuvoli.

Goltz's hypothesis, then, accepted for want of a better one, and repeated in all the physiological treatises, is entirely insupportable. According to Nuvoli, the ampullary nerve terminates in a manner precisely opposite to that upheld by Goltz. He affirms that the semicircular canals originated in three planes: two vertical and perpendicular and between them, the third horizontal and perpendicular to the first, and therefore corresponding to the three dimensions of space, are attached to the otolitic vesicle like three soft, flexible handles to a little mobile basket, like a pendulum in the perilymph. In the movements of the head and body the pressure on the otoliths, which, by inertia, are the last to follow the movement, will not be more exclusively and directly from above downwards, since it is not caused solely by the force of gravity, but is felt laterally on the inner surface of the vesicles in a direction opposite to that of the movement itself, and the membranous canal will be stretched. In the other termini the traction will be variously distributed among the three semicircular canals, depending in the direction of their planes and of the movement.

This traction of the semicircular canals provides an adequate physiological stimulus to the ampullary nerve terminals. Every movement of the body and inflexion and rotation of the head will provoke in each vestibule three ampullary sensations of different intensity, according to the different traction in each canal, by the perception of which the direction of the movement can be determined. This determination thus depends on two essential facts, namely, the special anatomical disposition of the three planes, and the varying intensity of the ampullary sensation. The three osseous canals have no other function than that of maintaining the membranous canals in their assigned planes. The otocyst remains the essential element of the whole vestibular apparatus, since it alone can satisfy the needs of the equilibrium and movements of the body, the semicircular canals integrating and perfecting their functions.

Let us now see the anatomical connections between the vestibule and the pneumogastric nerve. From its origin in the lateral sulcus of the bulb to its termination in the diaphragm this nerve furnishes branches to the thoracic and abdominal organs. Its anastomosis with the facial constitutes the auricular nerve of Arnold, with its two branches, one anastomosing with the posterior auricular nerve and the other being distributed to the posterior face of the pavilion and to the postero-inferior wall of the external auditory meatus.

Excitation and hyperæmia of the vestibular apparatus also produce excitation of the vestibular bundle with which it articulates. This vestibular bundle is excited directly by the specific peripheral sensibility of the vestibular apparatus, and indirectly by the general sensibility of the body by means of the cerebello-vestibular fibres which terminate in the nuclei of Deiters and Bechterew.

Experimental results are confirmed clinically, in that the vestibular bundle can easily become suppressed by slight and inadequate stimuli, mechanical, thermal and electric, and that a lesion in it may immediately produce serious oculomotory functional disturbance, with consequent disorientation, which persists as long as the abnormal excitation of the vestibular bundle lasts.

One of these inadequate stimuli is prolonged rotation of the body on its vertical axis. Rotation of the head and body within normal limits represents a normal stimulus for the otolitic vesicle and the semicircular canals which react with a corresponding normal reaction; when, however, the duration and speed of the rotation are excessive, as produced in a revolving chair, the stimuli, becoming inadequate, induce disturbance of the vestibular

apparatus, and consequently of the vestibular bundle with which it articulates. This immediately produces a disturbance of equilibrium even to falling, impossibility of walking, vertigo, nystagmus, nausea and vomiting. Similar phenomena occur when a current of air or of warm or cold water enters the auditory canal, causing excessive heating or cooling of the vestibular terminations, or when the poles of a galvanic current are placed within the tragus of the ear or on the mastoid process, inadequately exciting these terminations.

Conclusions.

Accepting a modification of Nolf's theory, I conclude that sea-sickness is a functional disturbance due to the hyperæmia of the vestibular apparatus, produced by the constant changes in the position of the body on the ship in movement (movements which have an opposite direction in pitching and rolling) by which at first the semicircular canals and the endolymphatic liquid simultaneously follow the movements of the body, and that when they have a movement in the opposite direction the endolymphatic liquid continues to be carried in the direction produced by the first impulse and then goes inversely to the movements of the semicircular canals, which follow all the movements of the body. In this way the endolymph is made to impinge on the ampullæ of the semicircular canals, producing vertigo.

Movements of the ship will excite different semicircular canals, especially of the superior and posterior canals (rolling and pitching). Excitation and hyperæmia of the vestibular apparatus produce a reflex vertigo with exaggeration of the activity of the pneumogastric nerve (vagotonic state). In these conditions the best remedies are those which act as sedatives to the vagus, and tampons producing ischæmia introduced into the external auditory meatus.

Numerous experiences have produced satisfactory results, which have been confirmed by means of criteria *ex juvantibus* the correctness of the ætiological theory.

Postscript.—Having submitted the preceding publication in homage to the great Italian clinician, Augusto Murri, he had the courtesy to reply in these terms:—

"The argument is as obscure as it is ancient, but your better knowledge and perspicacious observations have radiated much of the darkness which surrounds this phenomenon so common and so well known, though still mysterious. The importance of the vestibular nerves, of the vagus, of the semicircular canals and of the otolith has been clearly put. But the phenomenon of the equilibrium of the body is very complex. In addition to the canals, the vestibule and the vagus, there are at least two other phenomena yet to be explored: our consciousness of equilibrium lost or menaced, and the faculty of reacquiring it voluntarily. It is true that all this is physiology of the whole encephalon and not merely special to sea-sickness, but is there any sea-sickness without the cerebrum and cerebellum? I cite this that light may be thrown on it, not to cast doubt on the pathogenesis. . . ."

These observations will induce me to prosecute further researches, during which notice will be taken of Prof. Trocello's work.

Trocello (*Annali di Medicina Navale e Coloniale*, Nov.-Dec., 1916) treats at length the pathogenesis and ætiology of sea-sickness and concludes that the disturbances are not be be considered merely as labyrinthine vertigo.

It is a vertigo of general kinæsthesia in which the vestibule also appears to play some part. Vertigo is a phenomenon of consciousness and, in the case of sea-sickness, it is provoked by disturbance of the automatic centres of equilibrium only in that it is averted from the superior psychic centres. The cause of the kinæsthetic vertigo, according to Trocello, is always to be sought for in passive movements of the extended body, acutely, in a continuous and prolonged manner, to determine static and dynamic equilibrium; movements which occur in different planes, which are unusual for the subject and which possess accessory characters, such as brusque and fleeting vibration and interruption.

The conclusions of Trocello thus answer Prof. Murri's observations, and I agree that sea-sickness is a more general phenomenon. Nevertheless, it appears to me that sea-sickness is chiefly a vestibular vertigo complicated by vagus irritation. This is, however, not to exclude the insufficiency of the automatic centres of equilibrium (Trocello) which, without doubt, have a value not negligible, for the reason acutely stressed by Murri that sea-sickness cannot exist without the cerebrum and cerebellum.

In any case the practical result remains that medicaments which exert a depressant action on vagus tone and on the vestibule give the most brilliant results, and this is concordant with Trocello.

My experience and observations confirm the hypothesis already set forth, to which may be added insufficiency of the automatic centres of equilibrium.

Geographical Distribution of the Milkweed Flagellate, Herpetomonas elmassiani (*Migone*) (Francis O. Holmes, *Phytopathology*, May, 1925).—*Herpetomonas elmassiani* (Migone), previously known to occur in Maryland, was found to be present in the latex of milkweeds (*Asclepias syriaca* L.) as far north on the Atlantic coast as the northern boundary of New Jersey within a few miles of the Hudson River. Points in New York State and in Massachusetts were examined without positive results.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—**The Subscription, which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors **desiring additional reprints of their communications** to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE **should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF
Tropical Medicine and Hygiene
FEBRUARY 15, 1926.

SPIROCHÆTAL PULMONARY GANGRENE.

BRONCHIAL or pulmonary spirochætal infection was first described by Castellani in Ceylon in 1905. These findings were soon abundantly confirmed by many authorities and from many parts of the world. It has now been found not only in Ceylon, but also in India, China and Indo-China, the Philippine Islands, North and Equatorial Africa, being especially common in the Sudan, in the West Indies and in America. It has recently been encountered in various parts of Europe, mainly in the Balkans, in Switzerland, Italy, France and England. It would thus appear that the disease has quite a cosmopolitan distribution.

The brunt of the affection has hitherto been considered to fall on the bronchi, a form of bronchitis resulting, which may be acute, subacute or chronic in type. The acute type is often mistaken for influenza and malaria. Examination of the sputum for the presence of Pfeiffer's bacillus will distinguish the affection from influenza, and the examination of the blood for plasmodia will differentiate malaria. In the subacute and chronic types the presence of blood in the expectoration is so prominent a symptom that Violle termed the affection "bronchite sanglante." It is generally diagnosed in the first instance as phthisis and only after repeated negative examination of the sputum for tubercle bacilli and the recognition of *Spirochæta bronchialis*, which is generally present in very large numbers, is the correct diagnosis arrived at. From endemic hæmoptysis bronchial spirochætosis is readily distinguished by the absence of ova of *Paragonimus ringeri* Cobbold on examination of the sputum.

The causal organism was termed *Spirochæta bronchialis* by Castellani, and both he and Fantham consider it to be a separate species and quite distinct from the several varieties of spirochæta encountered in the mouth, either in health or disease. This view has lately been challenged, especially with respect to the organism found in cases of pulmonary spirochætosis where gangrene of the lung is apt to supervene, and evidence is now accumulating that pulmonary gangrene may be caused by spirochætes and fusiform bacilli aspirated from an unclean mouth, and that it may be prevented by proper oral measures, and the causal organisms can readily be found in the washed sputum. The ætiologic relationship of spirochætes and fusiform bacilli to pulmonary gangrene is evidenced not only by the predominance of these organisms in early gangrenous areas, but also by the fact that gangrene with death in a few days was produced in guinea-pigs by the injection into traumatized tissues of material from pyorrhœa alveolaris, dental caries, pulmonary gangrene and Vincent's angina containing innumerable Vincent spirochætes and fusiform bacilli. The relationship of oral spirochætosis to pulmonary gangrene is emphasized by the production in the rabbit of pleuropulmonary gangrene following the intrabronchial injection of material from dental caries containing innumerable Vincent spirochætes and fusiform bacilli.

In the course of two years Kline and Berger (*Journ. Amer. Med. Assoc.*, November 7, 1925) observed sixteen cases of pulmonary spirochætosis at the Mount Sinai Hospital in Cleveland, and consider that this number gives a better idea of the incidence of this condition than the fact that only

fifty-two cases have thus far been recorded in the literature of the United States. In five of the cases in which definite gangrenous necrosis with cavitation was present, arsphenamin treatment apparently prevented death and resulted in practically complete disappearance of symptoms. Five cases in which there was extensive pulmonary or pleuropulmonary gangrene, and in which no treatment was given or treatment when the patients were moribund, resulted unfavourably. In five cases in which there were less severe acute pulmonary lesions arsphenamin treatment resulted in prompt cure.

The onset of pulmonary gangrene in the course of any respiratory condition should then be suspected when the sputum becomes brown and foul-smelling, and there is an increase in the severity of the existing signs and symptoms. A diagnosis before any appreciable pulmonary destruction has occurred may be made by finding Vincent spirochætes and fusiform bacilli in the sputum after careful washing.

Spirochætal pulmonary gangrene is a distinct entity and can be prevented by eradicating the primary oral focus. It apparently develops as a result of the aspiration of spirochætes and fusiform bacilli from the oral cavity. It may be engrafted on any acute or chronic pulmonary condition, but is usually unrecognized, principally because its symptoms, although characteristic, are attributed to the primary disease. It is a grave complication, and if untreated is frequently the cause of death. Arsphenamin therapy is apparently a specific in this as in other spirochætal infections.

F. E. T.

Annotations.

Plague and the Regulation of Numbers in Wild Animals (C. S. Elton, *Journal of Hygiene*, October, 1925).—A short account is given of the occurrence of plague in wild mammals other than "domestic" rats and mice. Enough is now known to show that such epidemics are of great practical importance. The method by which most rodents regulate their numbers is as follows: increase in numbers over several years up to a point at which an epidemic of some sort occurs, which kills off a large proportion of the population. Increase then takes place again, and is followed by another epidemic, and so on indefinitely. These periodic fluctuations are probably controlled by widespread climatic fluctuations, the best evidence for this being that in certain cases the former run synchronously in widely separated countries. There appears to be a dominant short period in fluctuation of three to four years, and a large movement of period ten to eleven years, both in North America and Europe. The fact that the eleven-year-old sun-spot cycle roughly corresponds with the larger movement is significant.

The data available from Eastern Asia suggest that there, too, small mammals fluctuate periodically in numbers, and with similar periods to those of North America and Europe. There is also some evidence that the maxima of the ten to eleven-year fluctuations coincide in Eastern Asia and in North America, just as those of the three to four-year period coincide in North Canada, Greenland and Norway. Evidence is given that the plague marmot (*Arctomys bobac*), and other rodents carrying plague, are liable to these fluctuations. If this proves to be true it may be possible, when fuller data are available, to forecast with some accuracy the years of epidemics among these animals, and if this can be done we shall have some means of gauging the likelihood of the occurrence of plague outbreaks in the human population of those regions. The available data are admittedly fragmentary, but it is probable that between the years 1931 and 1934 epidemics among *A. bobac* in Transbaikalia and Mongolia will be severe, and that these events will lead to an increase of plague mortality in man.

Remarks on a New Flocculation Reaction for the Serodiagnosis of Malignant Disease (H. J. B. Fry, *Brit. Med. Journ.*, February 4, 1925).—The preparation of an antigen and its mode of employment in a simple flocculation reaction for the diagnosis of malignant disease are described. Tested in 500 cases of both malignant and non-malignant conditions a correct result was obtained in 75 per cent. Except in one case uniformly negative results were obtained in healthy persons. In the absence of malignant disease flocculation seldom occurs in syphilitic conditions, but a control Wassermann test is advisable. In acute febrile conditions, such as sepsis and tuberculosis, positive flocculation may be obtained.

The Relation of Herpetomonas elmassiani (*Migone*) *to its Plant and Insect Hosts* (Francis O. Holmes, *Biological Bulletin*, November, 1925).—Histological studies of the milkweed host of the flagellate *Herpetomonas elmassiani* (Migone) showed that the organisms were confined to the latex system, in which they were intracellular but not intracytoplasmic. The latex is secreted into the general cell vacuole of the latex duct, and it is in this that the organisms were found. No other cells or parts of cells were found to be penetrated. During the early part of the summer one or a very few latex cells in a plant were sometimes infected, for in *Asclepias* the original latex cells of the embryo never fuse. Because of this condition occasional localized infections appeared, in which a few leaves of the infected plant were found to be free from organisms. The flagellates of *Oncopeltus fasciatus* (Dall), a red and black hemipterous insect suspected of being the insect host of *H. elmassiani* (Migone), were found to inhabit the three-lobed thoracic salivary gland. In the gland these were definitely localized, colonizing only the dorsal and anterior lobes.

Leukoplakia Buccalis (Howard Fox, M.D., *Journal of the American Medical Association*, November 14, 1925).—Leukoplakia occurs chiefly in men, especially of middle age. It is rare in women and in full-blooded negroes. The essential cause of leukoplakia is unknown. Syphilis acts as a predisposing cause in the majority of cases. In a minority of cases such a relationship can be definitely excluded. Various sources of local irritation act as predisposing causes, including tobacco, alcohol, rough teeth, and gastro-intestinal disturbances. Of these, tobacco is undoubtedly the most important. Leukoplakia is a frequent forerunner of cancer, though it may exist for years or decades before the appearance of any malignant change. In the treatment of leukoplakia, prophylaxis is all important. The permanent cure of leukoplakia is difficult, the best agent for this purpose being apparently radium or the actual cautery.

A Bacillus of the Paratyphoid Group (Howard Anderson McCordock, *Bulletin of the Johns Hopkins Hospital*, December, 1925).—A bacillus of the paratyphoid group, apparently unencountered by previous investigators, is reported. Culturally it is similar to the other paratyphoids, but can be differentiated from them by its low avidity for rhamnose, failing to ferment this sugar in 24 hours, and the absence, or only slight production, of gas in all carbohydrates except xylose. Agglutination tests leave no doubt concerning its individuality, and agglutinin absorptions sharply separate it from the other paratyphoid types. The organism is pathogenic for mice, rabbits, guinea-pigs, but especially for rats. For the bacillus here described the author proposes the name *Salmonella muriotitis*.

Current Literature.

The Indian Medical Gazette. November, 1925.

A Note on the Value of Iodine Intravenously in the Treatment of Influenza (C. P. V. Shunker).—During the month of June, 1925, there occurred at the Central Jail, Bellary, an epidemic of influenza; sixty-six cases were admitted to hospital. All the cases were of the typical acute catarrhal variety. Twelve cases were complicated by lung conditions, pleuro-pneumonia or broncho-pneumonia. There were no deaths. Iodine used intravenously proved beneficial in the severe cases and brought about a marked improvement in the general condition of the patients in a short time. There is no danger attached to the method if the usual precautions are taken.

The Mosquito Factor in the Malaria of Assam Tea Gardens (C. Strickland).—Of the known malaria carriers which occur in Assam, *Anopheles funestus* and *A. aconitus*, represented in the paddy-fields, are very dangerous; probably during the rains *A. culicifacies* breeding in pools of pure water is also of danger; *A. maculatus*, breeding in spring water, cannot on present evidence be incriminated with doing much harm; *A. umbrosus* lurks in all undrained jungle, which should be viewed with great suspicion, and *A. jeyporiensis* takes no unimportant part in the causation of the disease. Of the measures for mosquito control, screening houses and especially clubs seems to be the most desirable, and an attempt should be made to sterilize the blood of children.

The Treatment of Malaria with Peracrina 303 (Wm. Fletcher).—Peracrina 303 is a chemical compound of acriflavine with a specific albuminate. The pills consist of a mass of yeast cells and a little starch, stained with a yellow dye, weighing about 10 gr. each. It is impracticable to administer peracrina for a long period and in the large doses recommended by the makers, and it is also too expensive for general use. The clinical tests made in Kuala Lumpur did not show that this product had any effect upon malaria parasites. The parasites may increase during treatment with peracrina and it is dangerous to employ it in the place of quinine.

Reviews.

An Elementary Course in Tropical Hygiene. Part I. By Mary G. Blacklock, M.B., B.Sc., D.T.M., Lady Medical Officer, West African Medical Service, with a Preface by Andrew Balfour, C.B., C.M.G., M.D., B.Sc., F.R.C.P. Published for the Tropical Diseases Bureau by John Bale, Sons and Danielsson, Ltd., London. 1926. Price 1s. net.

This booklet of forty-four pages is intended to form the first part of a school primer on tropical hygiene, and is written in the simplest language so as to be adapted to the needs of the child's mind, and the lessons are driven home by the presence of a few simple but arresting drawings of birds, flies, mosquitoes, and rats. After a few introductory lessons, the instruction is carried on in the shape of a story, which should serve also to keep the children interested. Dr. Blacklock has thoroughly succeeded in conveying the basic facts of tropical hygiene in a manner which should thoroughly appeal to her young listeners.

Department of Health Malaria Research Unit, Haifa, Annual Report, 1923.

The Malaria Research Unit of the Department of Health at Haifa, which is maintained by the American Joint Distribution Committee in co-operation with the Government of Palestine, has issued this excellent Annual Report, beautifully printed, well illustrated, and provided with good maps. The close correspondence in Palestine between the calendar year and the malaria season makes it convenient to adopt the former as the basis for purposes of control, compilation

of records, statistics and reports. The first part of this report deals with the control demonstrations, which enabled the Unit to obtain a considerable amount of useful information as to the prevalence of malaria in different parts of the country, its ætiology, nature of breeding-places, types of anopheles mosquitoes, &c., as well as serving as an excellent means of practical education of the public at large in the value of malaria control. The second and third parts deal with the permanent drainage work carried out by the Unit or by other agencies with Unit supervision, and with the work of the laboratory. We should be glad to see other annual reports reach the high standard of this one.

HANDBOOK OF TROPICAL DISEASES. By Many Writers. Edited by Carl Mense. Vol. I. 3rd Edition. 1924. Barth, Leipzic.

This magnificent volume constitutes the first volume of Prof. Mense's Tropical Diseases, which has now reached its third edition. It deals fully and systematically with arthropods and the diseases which they transmit, from the pen of Dr. Eysel, of Cassell, and with hæmatology as applied to tropical medicine, from the able pen of Dr. Victor Schilling, of Berlin. So well and thoroughly is the work done that this handbook may be looked upon as the authoritative German work on tropical diseases. Each section contains an extensive bibliography of the subject, in which it is gratifying to note that references to the English literature figure quite extensively. The illustrations, which number 341, along with twelve plates, of which five are coloured, are beautifully executed and constitute quite a feature of the work. A copious subject index completes this very fine and exhaustive treatise.

BATS, MOSQUITOES, AND DOLLARS. By A. R. Campbell, M.D. 1925. The Stratford Coy., Boston, Mass., U.S.A.

This curiously-named book contains some curious reading. The author, Dr. A. R. Campbell, claims to have made an intimate study of malaria, having limited his practice to that disease and typhoid fever. The book is divided into four parts. Part I deals with bats, mosquitoes, and dollars, and gives the title to the work. It discusses *seriatim* four statements or, as the author calls them, allegations, namely: (1) That the malarial mosquito is one of the greatest enemies of mankind. (2) That the bat is one of man's best friends, because it so relentlessly destroys the malarial mosquito, that insect being its natural and principal food. (3) That we can build a home for bats[1] in a scientific manner to meet the requirements of their most singular habits, and one which they will inhabit: a home where, being protected from their natural enemies, they will increase in countless numbers and eradicate the malaria in its vicinity; and (4) That each bat roost, in addition to its great hygienic value, is in itself a little gold mine, by reason of the cash obtained from the natural high-grade fertilizer, guano, which it will certainly produce. Part II deals with dragon-flies. Part III with bed-bugs and small-pox and the eradication of small-pox by other means than vaccination. Part IV describes the author's views on the functions of the spleen, whilst a glossary of technical terms used, couched in the simplest possible phraseology, indicates that the author had his eye on the general, rather than the medical, public when writing this book.

[1] A photograph of a bat tower, or roost, appeared in our issue of November 2, 1925.

MEDICAL EDUCATION. A COMPARATIVE STUDY. By Abraham Flexner. The Macmillan Company, New York. 1925. Price $2.50.

In this comparative study of 334 pages, Mr. Abraham Flexner has given a comprehensive survey of the state of medical education at the present day in the various countries of Europe, in Canada and the United States, together with a critical review of its progress during the last fifteen years. Mr. Flexner takes a wide view of his subject, and discusses in turn general education, the basic sciences, the curriculum, the laboratory sciences, the clinics, and the institutes for medical research. A chapter on the important question of costs is also included. This volume is the more welcome as so little has been written on this subject in English, and so much information has been gathered together in its pages, that it is absolutely essential to all who are interested in the subject of medical education, whether from the point of view of educational methods or concerned with the organization of medical schools in any part of the world.

PROCEEDINGS OF THE INTERNATIONAL CONFERENCE ON HEALTH PROBLEMS IN TROPICAL AMERICA (held at Kingston, Jamaica, B.W.I., July 22 to August 1, 1924). 1924. Boston, Massachusetts, The United Fruit Company.

The volume is a record of the proceedings of the International Conference on Health Problems in Tropical America, which met at Kingston, Jamaica, July 22 to August 1, 1924, by the invitation and under the auspices of the Medical Department of the United Fruit Company. Delegates were invited to represent universities, medical societies, health organizations and governments, and the list includes many names eminent in tropical medicine, both from Europe and America. Following the scientific sections at Kingston, the members of the Conference were given an opportunity to inspect and study the medical and sanitary work of the United Fruit Company in its divisions in Honduras, Guatemala, Costa Rica, Panama and Colombia. Following an address of welcome in glowing terms by Dr. Deeks, the General Manager of the Medical Department of the United Fruit Company, are seventy papers contributed by the members of the Conference. These seventy papers comprise a wide and comprehensive discussion of almost every aspect of tropical medicine and hygiene, each by an acknowledged authority in his subject. They afford much valuable information which no up-to-date practitioner of tropical medicine can afford to overlook.

Original Communications.

ANATOMICAL OBSERVATIONS ON THE YELLOW FEVER PROBLEM IN AFRICA.

By Prof. W. H. HOFFMANN,
Habana, Cuba.

SOME weeks ago, through the kindness of Dr. Young, I received the kidneys of four cases of suspicious yellow fever from Accra, Gold Coast Colony, West Africa.

The official reports of the recent epidemics mention twenty-six cases with eighteen deaths for 1923, and eight cases with seven deaths for 1924.

The organs reached me in a good condition as it is quite easy to send specimens of about 1 c.c. in size in a 10 per cent. solution of formalin by sample post in the small laboratory tubes generally used for the transport of fæces or blood samples.

In the anatomical material of twenty-eight cases of yellow fever I studied last year[1] I found the presence of casts of lime-salts in the kidney in twenty-four cases. My observations have been confirmed in a recent epidemic in San Salvador. In my opinion this lesion is very characteristic of yellow fever. So I was very much interested in studying the kidneys of these West African cases.

The four cases from Accra uniformly show a certain degree of parenchymatous nephritis with formation of hyaline casts often stained by bile pigment, especially in the secretory part of the tubular system.

The severe nephritic degeneration and the hæmorrhages and blood-casts, which are characteristic for yellow fever, were not present and I did not find any necrotic desquamation of the epithelium nor limecasts, which, in my opinion, are produced very acutely by infiltration of the dead cells with calcareous substances under the action of the specific powerful toxins of yellow fever, but in no other disease. The lime-casts would probably not be absent in all the four cases if they were yellow fever.

Fig. 2 shows the limecasts in a typical yellow fever case. Fig. 1 shows the kidney of one of the West African cases. The difference is evident.

After my study of the four cases from Africa I think that the lesions in the kidney do not correspond to those of yellow fever.

In one case I found many hæmoglobin-casts. This would suggest a case of a hæmoglobinuric fever rather than of yellow fever, which does not produce hæmoglobinuria.

Recently I have seen cases of a fatal disease which, even to an expert like Guiteras, clinically seemed similar to yellow fever. But Cuba has been free from yellow fever for almost 20 years. I had the opportunity of making the anatomical study of such cases, and was absolutely sure that they could not be yellow fever. An examination of the blood showed that the disease was caused by a severe infection with the parasites of subtertian malaria. The parasites were not only present in nearly all the red cells, but generally there were two or three of them.

Neither clinically nor anatomically is it easy to make the diagnosis of yellow fever in sporadic cases as in West Africa with absolute security, and especially to differentiate them from the hæmoglobinuric cases. I think it will often be impossible without the cultivation of *Leptospira icteroides* and the specific immunity reactions.

There is no doubt that a clinical picture similar to yellow fever in certain cases may be produced by malignant malarial infection, perhaps also by

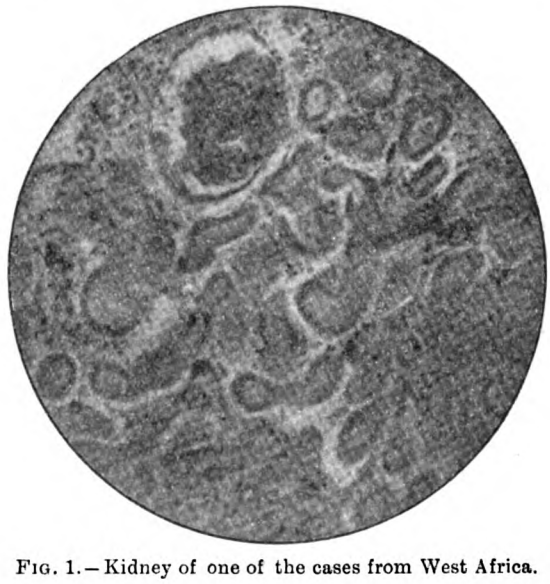

FIG. 1.—Kidney of one of the cases from West Africa.

FIG. 2.—Kidney of a case of yellow fever, showing the lime casts.

[1] W. H. Hoffmann: "The Histopathology of Yellow Fever," *Journal of Tropical Medicine and Hygiene*, 1924, No. 17, p. 235.

spirochætal infections or even by some still unknown leptospiral infections.

I know that this study must be necessarily incomplete, as the material and the information at my disposal are limited. After the anatomical study of these four cases I cannot convince myself that they are true yellow fever cases.

My arguments are of rather a negative character. What we really want is a positive proof—which I lack—that endemic yellow fever still exists in West Africa, because this alone will allow us to take the necessary international measures for its immediate control, which are indispensable, if it is present in some form or other.

This question is of such overwhelming importance for the epidemiological safety of the whole world, especially for America, that it seemed justifiable to contribute with such an incomplete observation to the discussion of the problem.

MALARIA IN WEST AFRICA IN 1893.

By G. Rome Hall, M.D.

The first acquaintance with this disease was made by the writer in 1893 at Lagos, West Africa, in the Colonial Medical Service. Although at that time Laveran had designated the mosquito as the greatest factor in its production, these views had not yet authoritative sanction: the School of Tropical Medicine had not been founded, and the exact link between the insect and the disease had not been established. It was about four years after this that the present scientific attitude to the disease began to develop.

At that time the new medical man did well to listen with respect to the views of the Old Coasters, their laymen experiences were worth studying. It cannot be said that the first trained medical men from the above school extended the same courteous hearing to those of their own profession who had been treating the disease not without skill, and not without a large measure of clinical success, of the nature of instinctive action that even in this day puts the general practitioner of thirty years' experience ahead of the man fresh from the schools.

You were told when you came ashore that your expectation of life was seven years; very few men then came out after thirty for the first time, the Colonial Office rarely sent anyone under 24. The white officials then served under a twelve months' term ashore and six leave; at that time you were fortunate if you did not spend over seven weeks over the two voyages. The commercial men were usually under a three years' agreement. Another bad point was that many were far too young in age, even under 20. The missionaries came out for a longer period, but generally had the advantage of a medical examination first; this was not the constant routine with the commercial men, but if the former came out at their own expense they were excused a proper standard. The mining industry had not then begun: perhaps a dozen white men were at Tarquah, on the Gold Coast.

Early Ideas of the Disease.

The name itself, the disease due to breathing evil airs, shows that for generations it had been associated with the odours of decomposition of certain localities, especially those of the swamplands. It had become accepted that if a man went ashore for a night or two at Sierra Leone, on the way out, then about a week from Lagos for the mail boats, that he would probably develop fever within a few days of landing. When there had not been this element of risk it was considered a certainty that fever, then a synonym for malaria, would show very soon if he did not protect himself against the sun by the umbrella at certain hours, and the helmet between eight and five. The former observation caused many old coasters to start taking quinine at Las Palmas in the Canaries, then a week from Sierra Leone.

This disease had been specially studied for over two hundred years in the West Indies; at least three peculiar facts stood out there. In the Guianas, with topographical characteristics apparently the same as West Africa, it was possible for children born of European parentage to grow up to maturity on the West Coast a very few years of early life was possible, and that not on the coastline. At a Basle mission in the grasslands behind Accra, and at a higher altitude than the coast, four children had been born, who had lived to go home at an early age. Also, exercise could be taken in the West Indies without harm that was disastrous on the Coast; cricket, played from early afternoon in the former, was impossible till after 4 p.m. But in Kumassi such was possible; it has an altitude of over 800 feet.

In the West Indian Islands it was noted how altitudes for many years free from malaria would suddenly develop it. In the present day you would look for the arrival of previously absent anophilinæ, or the advent of actively infected persons, if the former had been there before. Another peculiarity was that in certain observed localities it was stated that the disease could not cross running water: it occurred on one side of a river, and not upon the other. For many years Axim Fort, on the Gold Coast, had the reputation of being one of the healthiest official stations, and Kwitta, at the other end, about the worst. The fort stands on a small promontory jutting out into the sea, swept by the prevailing breeze coming straight in off the blue water; the small swamp on the landward side was some sixty feet below, the drift in the harmattan land breeze was into the bay. But Kwitta was on a sandspit some twenty miles long, with swamps some miles deep behind it, and the prevailing south-west wind came over them on to the town. Personally mosquitoes gave me but little trouble, for four spells on the Gold Coast I slept without curtains, but only one night there: a specially malignant breed existed, marked both for pertinacity and size.

Other points had been noticed. That the devitalized white man who had got over his seasoning

ver, as the natives called it, was a much better roposition to his employers than the newcomer ith his European vigour unspoilt. In fact, if the mer was a specially fine specimen of manhood, e was regarded as more likely to have a malignant ttack. The equivalent experience was well known ears ago on board ship, when the finest men would ddenly die from pneumonia, being overboard ithin 48 hours of being ill. The reason was the me: being of high resistance they stood up and pt on duty through the early stages of the disease til they crashed. In expeditions where white en had been employed it had been recognized that e Guardsman type was nowhere in ultimate resist-nce, when ill, to the short stocky man of good est physique.

It was considered that service in India and alaya did not give a man a better chance in West frica, rather the reverse; the exception was that e old Dutch official stood the change well. The robability was, we know now, that the man of the mer experience was not only devitalized, but had enign infection, whereas the latter was a survivor om the malignant infection at Batavia and neigh-ouring places. The Dutchman was reputed also o study himself as regards exposure to the sun, voiding it as much as possible, and travelling at ight by boat as much as he could when he had to ass between his coast stations.

This state of devitalization was a very real con-ition of health; to a definite extent you had to alter your constitution. A certain degree of anæmia came on: it was a saying that West Africa bleached you, but did not bronze you. From want of mus-ular exertion, and, we know now, the atonicity aused by latent infection, there was a softening of issue generally, but one result was fewer waste roducts except on exertion to cause trouble if atabolism went wrong. Cardiac action shared in his want of tone by irritability on exertion, he respiration became shallower, easily passing into uickened arhythm. The diurnal health variation f temperature was more marked than at home: p to 99·2 was normal in the sun before profuse erspiration came on. The skin in health was lways moist, with visible perspiration on exertion, r out of the breeze in the daytime. In my case it ever ceased until the temperature sank below 9° F. The skin became paler, the epidermis hinner, and the glands more patent. This pro-use transudation on exertion meant that a man went about with a cold water jacket around him in the shape of a skin under blood-heat; in my own ase the skin often registered three degrees less than the mouth, even five on special exertion in bad health. But these remarks only refer to those who had undergone a change of constitution; until you had done so you had not become acclimatized. When these changes had occurred there was rela-tive safety; a man without a minor enlargement of the spleen was not safe. An old coaster's welcome to a newcomer was: "Well, we will know in six months if we are going to keep you." This change might be arrived at in two months if there was a severe seasoning fever within that time; if in reasonable health you might last out nine months, as in my own case.

When that time arrived the profound change that had occurred in metabolism was shown by the fact in most cases that the normal motion had ceased to be passed in rouleaux, but without shape and semi-fluid; this was ordinary in the native. The urine on standing a short time became alkaline, at any time it tended to visible formation of phos-phates, and sometimes was eliminated alkaline, remaining so at home occasionally. It is believed that these remarks do not of necessity hold good in coast life now: reasons will be given further on.

The Social Effects of Malaria.

As has been shown over and over again by reports from the School of Tropical Medicine, the whole development of the moist tropics was held up by this disease, by its effects on both Europeans and natives alike. We know now that there were two other fevers often mistaken for varieties of malaria, or concurrent factors in its incidence—sun and yellow fever. A person who has suffered severe sun exposure, either acute, or slighter and more chronic, has his resistance to other infections, acute or latent, greatly reduced: this was well recognized as a clinical fact. Sun fever is personally regarded as a breakdown in the processes of blood-albumin metabolism, that such stops short at the first stage of albuminoses, these accumulating in toxic quan-tities. When it is remembered that albumins *in vitro* coagulate at 140, and that the solar heat is usually at midday 155 at least, and this in a super-moist atmosphere, it is easily seen that resistance must be kept specially high. The most marked feature is that the temperature goes up, and keeps up with minor fluctuations, the cerebral disturb-ance is more marked than in malaria, and the skin has a constant pungent dry heat, perhaps for days. Any attempt to force it into action with sudorifics is hurtful: diuretics and slight stimulation seem to give the best results. It is as if the morbid pro-ducts formed have to burn out before the secretory action of the skin returns.

The other disease was yellow fever: in the early nineties it was regarded as a malignant form of malaria. When men who had seen this disease in the West Indies began to serve in West Africa, doubts as to this diagnosis began to be made, but the older view was strenuously upheld by the execu-tive. It fell to my lot to report a case at Cape Coast, where it constantly occurred, in 1903, to have my diagnosis repudiated by those who had never seen the case. The result was that my report was sent to the Colonial Office, my statement being that there was no disease more amenable to preven-tive measures, if recognized. Although we were then told that it was a disease originating in the West Indies, statements made by my native dis-penser led me to report it as endemic in the West African bush. My attitude was justified when the

Commission reported some three years after that these terrible exacerbations of disease were yellow fever, and that it was also endemic: also when a request was made by the Tropical Section of the B.M.A. annual meeting in 1911 for my views on the subject.

The incidence and relationship of blackwater fever to malaria was gone into by me in an article on " The Metabolism of Blackwater Fever " in the April number, 1923, *Journal of Tropical Medicine*.

Owing to Lagos being on a small island, and burials perforce local, it was possible to obtain some information as to the native death-rate, as well as that of Europeans. There were no accurate means of obtaining the percentage rate amongst the latter, but that among the natives in the seven years ending 1893 appeared to be about 40 per thousand, pretty much that of England before the days of the modern science of medicine. 1894 was a bad year, starting with a burst of yellow fever, as we now know it to have been, 31 deaths occurred out of an estimated white population of about 150. A comparison of the deaths for the seven years previous showed that the Germans and French died off at twice the rate of the British; the former had not attained to the tropical instinct, there was decided evidence in Duala in 1915 that they had been apt learners. For both these nations the hours of work were far too long, there was absence of exercise, and in the evening lager beer in the one case, wine in the other, and other social activities, were not conducive to the retaining of a high resistance.

Soon after the completion of the war a Committee sat on the Gold Coast to review the health of the Europeans, statistics were compiled for about twenty-one years on either side of 1897. This date coincided both with the development of tropical medical science and with the influx of Europeans to the Gold Coast owing to the mining and other industries. For a term of twenty-one years prior to that date the mortality for the Gold Coast was 75 per thousand a year; for the same time afterwards it was 18, about an Indian rate. Since then it has improved, having been down to 12 per thousand a year. These figures need criticism to obtain a fuller understanding. They refer to generally picked lives, passed as fit to come out, and to early manhood or womanhood, and to early middle age. Invalids, either of chronic variety, or convalescents after grave illnesses, are sent away to recuperate. In 1893 there were perhaps 200 white people in the Gold Coast; now there are over 2,000, half of whom live in the healthy upland zone, where perhaps only a dozen lived before 1897.

Alteration in Methods of Life.

My first voyage out gives some idea of the stage of civilization existing. A man who did not possess scholastic or other resources regarded service there as a variation of purgatory that would stand him in good stead in the future. The commercial men and the missionaries were a little better off; not so many of them had to live isolated lives as the officials. Not that two white men in a stati were usually better off than one: general inco patibility, or climatic neurasthenia, often preclud friendliness.

The ship was a mail steamer, saloon over t stern, cabins opening direct into it, one bath for to thirty passengers. Oil lamps in the cabins, electricity, no fans, no ice, and therefore limi variety in rations. No sick quarters for passeng or crew; that did not come for some years aft Cabins of about 400 cubic feet, holding on occasi four people, with practically no ventilation exc the ship was moving; even then the lattice arran ment might face the wrong way.

On shore the white men's quarters were ran away from the proximity of native huts; the G man researches in the Cameroons showed eve native child up to four at least an acute dan centre for malarial infection. Where the old fo had reasonable isolation they had danger cent in the storage of water in cisterns; into these rain water ran through uncovered entrances. T first bungalow erected with a " tin " roof was t old cable house at Accra; it obtained a very b record for health. On one occasion there were fi men resident; one died, and another was post by from the cable ship in the roads. He and t others died within two weeks, making one survi out of five. Iron rain-water cisterns had been su plied with unprotected entrances, the water falli into them from the unconnected spouts. Elmi had also a bad repute; the Mission had the us cisterns, and the Castle ones that locked, but whi were open often two half-hours a day. Cape Co was a hopeless hygienic problem until a standa cistern was brought in. The natives stored wat in huge jars sunk in the ground; these were neve emptied from year's end to year's end. Also, very large number of the native houses had met gutters; these inevitably sagged. No nati mechanic believes in accuracy for its own sak they were breeding grounds even in harmatt weather if there was condensation moisture. Ca Coast added on two other elements of trouble, ha shale and quartzite ground soaking in heat all t day; on radiation this was blanketed down by t super moist ground stratum of the air. There we records sometimes of weeks with only six degre variation between maximum and minimum shad Also, in ground of this formation, the town sprea ing over several hills, there were many pockets the hillsides filling with moisture in the rains.

There is one official record of a European infant company being sent there nearly a hundred yea ago; their women and children accompanied them one survived at the end of a year.

If housing was bad, recreation was in the sam position, pretty much that of the early Victoria era at home. There were rarely sufficient Eur peans in a station to form even a cricket team There was one at Accra, also tennis there and Cape Coast and Saltpond. There was no club: th Accra one was founded in 1897. Very rarely di

portunities exist for hunting or fishing. Golf as unknown.

Feeding was so defective that it is no wonder a ge amount of alcohol was consumed; beer was t considered to be beneficial. Champagne was e only wine drunk except after illness: it cer- inly had a rallying effect when a man was fatigued a day's exertion in the bush that nothing else d, and in cases of acute exhaustion was often sidered to ward off the development of black- ter fever. The cost of transport prohibited soda ter in the bush, and sparklets had not come in. was unknown.

For years the old coasters had acted on the prin- le of native food in the morning and European d at night: it was a case of survival of the fittest. now know that explanation was the vitamin-con- t of the former, and its grave absence in the ter as then available; the staple native food was undnut or palm oil soup.

The natives make the latter from the whole fruit; is a drupe, with the vitamin in the pericarp, it is t in the oil made from the kernel, and the sub- tute butters at home will be good or not accord- to which oil they are made from. The ground- t makes a soup like peasoup, the kernels, with ir thin outer skin, are roasted whole and ground , the vitamin is thus preserved. Against this, ich gives excellent health to the native, the white an's diet could only place tinned lard, tinned tter, and eggs whose yolks had depreciated ually through exposure to the sun. Bacon was erally tinned; smoked hams did not keep long the coastline.

The protein foods were fresh fish on the coast, ned in the bush, tough mutton and goat, and ngy fowl, except at the Kwitta end, where the unas reared on their grasslands cattle, sheep, ultry, ducks, and turkeys. But since meat led in the morning at 4 a.m. had to be eaten the ne night, it meant that butchers would not kill two or three white men alone. Where cattle e got through from the north they were not ed on the coastline except there were sufficient ple to underwrite the animal for one day's con- mption. The coast animals and fowls were rly devoid of fat, and none of the ordinary fish e oily. Frozen meat and frozen vegetables e unknown, fresh vegetables could not be ught from the islands owing to the long coasting ages then usually made even by the mail amers.

The native obtains his starch from bananas and ntains and fresh maize cobs, the young grain ng eaten whole. His root crops are yam, cas- a, and sweet potato; they were rarely eaten by cials, there being a prejudice against native hop." The only chance they had for anti- rbutic vitamin was in lime drinks, if taken. The ive soup had fufu balls like dumplings, made of ier grated yam, plantain, or young maize. ainst this native supply of vitaminized foods the ropean could only place white flour and polished .

The Old Treatment of Malaria.

It was natural to attempt to form a working hypothesis as to what this unknown disease might be, for successful treatment some theory is better than none. It was known that in addition to the first definite acute attack that the following conditions caused returns, that it was reawakened latent infection was not thought of. Over-exposure to sun and chill were the principal causes, the latter usually being due to sweat-soaked clothing drying *in situ*. Excessive fatigue, in the absence of either of the above two causes, and persistent high pressure brain work caused returns; the natives attributed most of their slighter attacks to constipation. Another cause held definite belief, acute and prolonged exposure to swamp and filth effluvia.

It was well recognized how alcohol and tobacco even in small quantities caused a relapse after an acute attack; if taken during the days of instability that followed. They were forbidden for usually the first day; tobacco was feared more than alcohol.

One of the medical men sent out soon after the Tropical School of Medicine started was really irate when the above causes of malarial attacks were stated; the tendency then was, and for long afterwards, to ignore the human factor, as we then called it, now known as "resistance." It was a case of the plasmodia, the whole disease due to plasmodia, and nothing but the plasmodia. In all these causes of recurrency the same factors are at work, the altered supply of leucocytes and opsonin and antigen products. The same kind of opposition existed from higher authority to the statements that the bad spells equally followed very wet seasons and those in which the rains nearly missed: in the latter the mosquitoes became concentrated in the white man's cisterns and in the natives' collecting storage pots.

The best hypothesis was that the fever followed on the accumulation of waste, of *materies morbi*, in the system: that ordinary elimination failed, and they had to be combusted off in the blood, while the skin was out of action. In the absence of known infection it was considered to be a disease of metabolism simply; the only difference now is that a specific reason for such is now known. It was also a matter of everyday and clinical observation that a man's electro-vital processes, as we would now say, became much more unstable and of greater irritability than at home, with greater tissue break-up. It was allowable from this to conclude that any fever process would be of greater intensity. These facts still remain, but a deeper cause is known. In my own case records were kept for three weeks on board ship, where circumstances could be controlled, of the amount of urea excreted per diem; not only was the amount at any time greater than at home, but on the days when no quinine had been taken the amount was about twice as much.

In 1893 the new antipyretics were coming into use: those available were antipyrin, antifebrin, and phenacetin. We would be called in to a man with the typical onset, rigors, fever, dry skin. In a

straightforward case, where the patient was not badly asthenic, and showed no cerebral symptoms, we thought nothing of a temperature under 105° F., especially if he had recently been taking quinine. If there had been a prolonged course of some weeks we expected a modified attack: it might be down to a single attack of a few hours. This was my own case, the exciting cause having been an accident which stunned for a few seconds in the fifth week after first landing. Or, if less protected, and with diminished resistance from unhygienic living, it might only be of three or four days, with several hours' exacerbation each day and complete intermittency in between. A bad case was one where there was a week or more of fever, never down below 102° F., with exacerbations up to 106° F. The degree of severity could be well compared to those of the ordinary febrile cold, slight bronchopneumonia, and lobar pneumonia of a severe type. Further experience led to the addition of another analogue—pneumonic—with a septic element in it; these we then called malignant malaria. Many of such are now known to have been yellow fever.

Our first object in treatment was to diminish waste of strength in every way, and to establish perspiration, as we then always found the temperature fell. If this could not be done we controlled by sponging the skin; in any case we gave complete rest to the patient; it was better to treat this stage in a native hut than to race the patient away in a hammock, which prevented reduction of the temperature.

Not four years ago, when seeing malaria again in West Africa, a new school man said, "Whatever do you want to produce perspiration for? I have been taught what you are aiming at is to kill the protozoa." That, it is submitted, is the result of laboratory study of disease, neglecting the patient factor, and his capacity for resistance. By so much as you did control and diminish the processes of waste, by so much was the patient's resistance the less entrenched upon, and by so much did he respond to the quinine given to kill the plasmodia, or reduce it to impotence for a time.

We gave antipyrin only to sthenic patients, and then only to those vomiting badly, as it would dissolve and antifebrin not, always guarding its depressing effects with a tablespoonful of spirit. Where the stomach promised to retain it we gave antifebrin by preference, reserving phenacetin for the asthenic cases. My personal method was, finding a patient over 104° F. to bring him down to under 102° F., when the waste of strength would be reasonable. If not over 102° F., to bring down to 100° F. One cardinal rule was never to reduce a patient to normal by drugs, a certain amount of pyrexia being regarded as curative, as combusting off waste. Having controlled the temperature, then came the time to put in quinine. Personally my view was that ten grains antifebrin had the effect of fifteen of phenacetin. If the temperature remained obstinately high a second dose would be given one hour after the first, but after that, if needed, at four-hour intervals.

In cases of blackwater, or of suspected malignancy with low temperature, a febrifuge mixture was given, the G.P.'s standby of pot. nit., pot. bic., sp. æther nit. Modern therapeutics can hardly improve upon this mixture, whose value was first proved by rule of thumb practice; it is diuretic and gently sudorific, it increases the alkalinity of the blood, and stimulates the ultimate circulation. Hippocrates himself would have approved of it.

Another method of control was through the skin itself, by direct treatment of it. A patient straight in from the bush, or one of unhygienic habits, needed a rub down with soap and flannel first to give his skin a chance of acting to drugs. This was all the more needful as the antipyretics indicated pushed up the temperature a little, while the skin remained dry; this further rise did not come down until there was a diuretic instead of a sudorific effect. If the patient had cerebral excitement the routine was to sponge him steadily with cooling lotion until the temperature fell. In the absence of ice, water as cool as possible was obtained and mixed with vinegar and limejuice. The head was kept cool with it, and the limbs sponged steadily from the extremities towards the trunk, the idea being to drive the blood into the trunk, as well as to return it cooler to the general circulation.

In hyperpyrexia the hot blanket bath was given, as also in asthenic cases of lower temperature, where drugs could not be pushed. The cold pack was only used for cases nearly *in extremis*, when all other attempts at control had failed.

Eggs, Ideal milk (there was no animal source), and Brand's essence were given. Quinine, then in the forms of the sulphate or hydrochlorate, was administered as soon as the temperature appeared to be controlled. Personally, my own practice was never to give more than 30 grains in a day. Fifteen grains at a dose was a maximum; in stomachs intolerant of it, five grains every few hours. Tabloids were reserved for prophylactic use if acute cases could not retain it in solution; it was tried in powder form in unsweetened condensed milk: cow's milk would be the ideal. On the second day of a controlled fever the prophylactic use was commenced; the period of exacerbation was expected generally between noon and three o'clock. Not believing in a bigger dose than fifteen to a man with coast cardiac atonicity, my custom was to divide it, fifteen at 7 a.m., ten at 11 a.m. This because experience seemed to indicate that the effect of the quinine nearly ceased in about eight hours, and that it produced appreciable effect in about four. Hence, if the fever exacerbation was expected at about noon (now we know it is due to the cumulation of the sporulation process), the first quinine was producing a marked effect by noon and finishing by about three. The eleven o'clock dose produced, then, its best effect as the first passed off, continuing up to early evening. The Germans in their experiments at Duala gave up the one big dose a week as a prophylactic in place of smaller repeated ones.

In convalescence these doses were tailed off by

gr. a day. First day, 15 and 10; second, 10 and 0; third, 10 and 5; fourth, 5 and 5; fifth, 5. further continuance depended upon the quality of he convalescence or the work being done. It enerally meant that quinine was now stopped until here was considered to be need for it; but in first ase fevers of newcomers my view was it should be ontinued until they had acquired the tropical constitution, one sign of which was a physiological ypertrophy of the spleen.

The conditions which were regarded as needing a enewal of the quinine for some days at least were he following. If any evening a man had a feeling f being specially well, preceded by yawning and a marting of the conjunctivæ, he was warned by old oasters to look out. We now know that this marked he pouring out of a minor amount of toxin, enough o act as a stimulant mentally. He was also warned f he was about to proceed on onerous work, or an ltered course of life, which would make demands pon his strength, or if he had minor ailments we ssociated with malaria, as rheumatic neuralgias, nyalgias, or colitis indigestion. It now works out, iven a latent infection prior to malaria, if malaria vas also acquired, that the resistance to the former me will break down if the latter becomes too active. It is submitted as a proposition that the ordinary man will speed up to furnish antigens and opsonins o meet three infections, but he cannot go further. In this consideration tobacco and alcohol are both regarded in excess as producing substances tending to their toleration. Since many of us acquire two out of these four, tubercular, rheumatic, streptococcic, or bacillus coli infections, it follows that a man who receives the malarial protozoa is weighted to the full without excess in alcohol or nicotine.

It was noticed on my first leave home, in midwinter, how quinine failed as a prophylactic; the observation has been repeatedly corroborated since. It was as if, being denied sudorific effects upon the skin, it was unable to function properly; arsenic seems to be the standby in the winter at home. But quinine is needed as a prophylactic when an attack is impending, or passing off.

In the days before the modern antipyretics quinine appears to have been used in large doses as a sudorific, twenty and thirty grains being nothing unusual. It is considered that the side effects produced by such doses neutralize any result possible before sporulation is effected. It was soon recognized that there was a form of malaria where the lowness of the temperature was in direct ratio to the gravity of the case, and where quinine was emphatically contra-indicated.

The fact that there are now estimated to be over a quarter of a million of men at home who have had malaria is the excuse for this reference to a vaso-motor form of the disease, as it appears to be to me. One point to be remembered is that a person may leave a malarious country with no definite history of malaria, but with the infection latent. If, as in the war, he was leading a hygienic life, especially if he took a course of quinine, the invading attack might be mistaken for a touch of the sun, a bad cold, or an attack of neuralgia. Worry, small bedrooms, and bad feeding, caused many an ex-soldier to blaze out with malaria his first winter at home. Blood examination will not show the protozoa, unless the specimen has been taken in the active stage; the tropical crescent infection is considered to lurk in the splenic and hepatic circulations, and only to be found in the peripheral blood during the sporulation process and pyrexia.

Quinine is useless as a prophylactic in the crescent infection except when the protozoa have returned for a time to greater vitality, some error in metabolism having provided them suddenly with eagerly utilized sustenance. For a few days after an attack quinine will do good, roughly as many days as there has been pyrexia, but after that a course of arsenic is indicated.

Thirty years ago, before the infection was understood, we were told that it needed at least seven years for the West Coast malaria to die out of the system, and that any acute attack during those years spun out the time further. This my own health has proved, as also the existence of this vaso-motor type, which still crops up on changes of the weather. The practical point about this condition is this. In private practice, if it is not recognized, a man's resistance capacity is constantly entrenched upon whenever it is present; his resistance to other infections is gravely diminished. The condition runs thus, and is due to toxin of a modified nature being created.

Marked cardiac irritability, sometimes with extrasystoles, not yielding either to rest or cardiac drugs, but yielding immediately to five grains of quinine, twice or thrice a day. Together with this is decided mental instability; some wives have commented upon how "ratty" the husband gets before an attack. In some cases they have regarded profuse perspiration, especially if of the aceto-acetone odour, as a warning sign. But the definite symptom, in addition to the above, is the sudden onset of cold, blanched hands and feet, perhaps passing into hot extremities after a time.

The Present-day Coast.

The writer saw it again for a few months in 1921-22, a very different place from 1893. There were even white men there who appeared to have in no way lost their European vigour; there were white girls, recently at school, going out to, or with their parents, as if it was India. One white child of five was out for six months on the coastline, leaving for home apparently no worse. This point ought to be mentioned about white women. Even in the bad old days the Sisters of the Sacred Heart, and the wives in the Basle and Bremen Missions, were able to stay out much longer than the wives of the officials or commercial men—the latter rarely stayed more than eight months. We could only conclude that the former did so because they led non-society lives; some of them stayed out for years.

The Gold Coast was known to me when there

were no railroads, and about twenty miles, perhaps, open to wheeled traffic. Transport is revolutionized now. Therefore the provision of cattle and vegetables from the upland zones, and from ice chambers from the shipping. Clubs exist in all large towns, and the medical and sanitary services have a proper opportunity to serve the community according to modern scientific needs.

There were many improvements making for health, but one stood out above all others. In the old days white men never thought of going more than a few yards in the sun between nine and four o'clock without the shelter of an umbrella; in 1921 an umbrella was hardly ever seen. Going over the whole ground of why this greater resistance to the sun, the answer appeared to lie in the present custom of taking five grains of quinine every day from landing until leaving, instead of as before, constantly only the first few months, and on occasion after as then judged needful.

Emetine Hydrochloride in the Treatment of Oriental Sore. Notes on a Further Series of Cases (H. C. Sinderson, M.B., Ch.B., M.R.C.P., *Transactions of the Royal Society of Tropical Medicine and Hygiene*, October 15, 1925).—In two series of cases the author has treated in all 147 sores, and in only one has the result been disappointing. The uniformly successful results obtained in the way described by the author do not only indicate the great value of emetine hydrochloride in the treatment of Oriental sore, but further, they give the drug strong claims to being considered a specific remedy for this disease.

A Disease in Wild Rats with Gross Pathology Resembling Plague (Public Health Reports, September 18, 1925—N. E. Watson).—There has been observed among the wild rats of Oakland, California, and the neighbouring cities, a disease the gross pathology of which resembles plague in rats. The specific factor in the disease is apparently one of the hæmorrhagic septicæmia group, which produces acute death in inoculated guinea-pigs, wild rats, and white rats, with resultant lesions resembling somewhat very acute plague in these animals. The practical importance of the disease is the difficulty it interposes in the routine diagnosis of plague in rats. The difficulty arises because of the similarity of plague lesions and those of this disease in the wild rat and because the presence of the disease in a plague-infected rat frequently results in the premature death of the inoculated test animal before the lesions of plague develop and before the plague organism has become widely disseminated through the tissues. The sanitary significance of these findings is as yet uncertain, since the pathogenicity of the hæmorrhagic septicæmia group, other than that of *Pasteurella pestis*, with regard to man is unknown.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed to the **Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent to the **Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings** per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

SYSTEMIC BLASTOMYCOSIS.

SYSTEMIC blastomycosis, the first case of which was reported by Busse and Buschke in 1894, is now recognized as a definite pathological and clinical entity.

The onset varies in different cases. Frequently

there can be elicited a history of a severe cold with cough, often with expectoration of blood-streaked sputum, though in a few instances localized painful swelling of an extremity or joint from secondary involvement appeared to be the first indication of infection. These cases seem to be due to pulmonary infection, and are often severe and rapidly fatal. More rarely the primary or principal lesion is an ulcer of the skin or a subcutaneous abscess without evidence of involvement of the lungs. In a few cases, moreover, the infection, while ultimately deep-seated and more or less extensive, does not seem to have become systemic, but to have spread progressively by direct extension or by metastases through the lymphatics without involving the deeper organs.

At the fastigium a typical case is not difficult to recognize, or at least to suspect. The outstanding features are essentially those of pyæmia. There is usually an irregular fever accompanied by chills and sweats. The skin and subcutaneous tissues are often extensively undermined by numerous large abscesses. Involvement of the osseous tissues is common and frequently widespread. Pulmonary implication is usually an early and characteristic feature, the persistent cough producing large amounts of purulent, often blood-stained, sputum. Pus or sputum mixed with 20 per cent. potassium hydroxide will usually reveal the blastomycetes, which appear as yeast-like, double-contoured budding organisms.

Once established, the course of the disease is usually subacute or chronic. So long as secondary infection is prevented, toxicity is seldom marked, even in severe and extensive infections. The patient usually emaciates more or less rapidly, becomes extremely weak, and ultimately dies of exhaustion or of some intercurrent affection.

Necropsies have amply demonstrated the systemic nature of the infection, and have also shown that certain organs or systems are more prone to extensive involvement than others. The most striking and characteristic feature of advanced systemic blastomycosis is the wide range of organs involved and the multiplicity of the infective foci not only in the same tissue, as for instance in the bones, but also in the different tissues and organs. This widespread dissemination is characteristic and the metastases are now believed to occur principally through the blood-stream. In view of these facts it is particularly interesting to note that the brain and meninges, especially the latter, are rarely implicated in the process.

Wilhelmj (*Amer. Journ. Med. Sci.*, May, 1925) emphasizes the infrequency of meningeal invasion, and points out a small group of cases to which he adds one of his own, which should be considered clinically as the primary meningeal form of systemic blastomycosis. In order to substantiate more forcibly the difference between ordinary systemic blastomycosis, with or without meningeal involvement, and the latter type, he analyses systemic blastomycosis with special reference to the onset and organs involved at autopsy, and he finds himself fully justified in recognizing a primary meningeal form of systemic blastomycosis which may occur without gross clinical evidence of systemic invasion.

Annotations.

Observations on the Employment of Anaerobically-grown Bacillus dysenteriæ *Shiga as a Vaccine* (*Journal of the Royal Army Medical Corps*, Brevet Lt.-Col. H. Marrian Perry and Major C. J. Coppinger, October, 1925).

Suspensions of *B. dysenteriæ* Shiga cultures under anærobic conditions can be inoculated into man and animals in relatively large doses without the production of any excessive reaction, either local or general. The effect of such inoculation is to produce in the blood agglutinating and complement fixing antibodies to an extent which is comparable with that following inoculation of Shiga bacilli, cultivated under ordinary aerobic conditions. There is some evidence to show that an animal inoculated with the suspension of anaerobically-grown organisms is capable of withstanding doses of a suspension of aerobically-grown bacilli which were fatal to unprotected animals. A mixed vaccine, consisting of bacilli of the mannite-fermenting dysentery group, together with anaerobically-grown Shiga bacilli, can be administered to men without causing a greater reaction than that following typhoid-paratyphoid inoculation and produces demonstrable agglutinins for both types of organism.

Some Observations on Malignant Tertian Malaria in Trinidad, B.W.I. (Eric De Verteuil, M.B., B.S., *Transactions of the Royal Society of Tropical Medicine and Hygiene*, October 15, 1925).—The conclusions of this interesting article are that prompt and early injection of quinine, in cases of malignant tertian malaria, may be most satisfactory, its delay may lead to the bitterest regret. In adults an intramuscular injection of 25 to 40 gr. of quinine bi-hydrochloride is usually given, according to the severity of the case, repeated within six to nine hours; after which oral treatment can usually be started in those surviving. There should be no hesitation in continuing the injections in obstinate cases. In *children*, those up to one year can usually be given an intramuscular injection of 5 gr.; to those from one to three years one of 7½ gr.; from three to five years of 10 gr., and from five to ten years of 15 gr. In each case the injection is repeated in six to nine hours. More than two injections may often be necessary. These must be intramuscular, not subcutaneous. I have particularly noticed how remarkably well children stand quinine, and have never seen any ill effects from its use, except for necrosis of the tissues, which sometimes occurs after injections. I have no experience of the intravenous method. There can be no doubt that the malaria of the West Indies is

similar in origin and in development to the malaria of Central America. The results of adrenalin in the treatment of vomiting are remarkable. In bad cases an injection of five to eight minims of the hydrochloride (1 in 1,000) will often put an immediate end to all vomiting and nausea; with moderate vomiting the oral administration of eight minims in 1½ oz. of water will prove just as efficacious. It has also been used as a routine in the usual quinine mixture for all cases of malaria (4 minims to the dose and giving three doses a day for four days), and there is reason to believe that it helps materially in the quicker recovery from all the usual distressing symptoms—the patient being able to take the mixture much more readily and to eat more heartily than had previously been the case.

The Pathology of Diabetes with Special Reference to Pancreatic Regeneration (Shields Warren, M.D., and Howard F. Root, M.D., Reprint from *American Journal of Pathology*, July, 1925).—A new interpretation is offered of the pathology of the pancreas in diabetes mellitus. The long continued action of an injurious agent (or possibly excessive functional activity) causes a gradual destruction of island, and at times of acinar, cells. New cells are formed to take the place of those destroyed, only to be exposed to the injurious influence with consequent pathological change. Their injury is followed by the production of still more new cells. Eventually the destructive process wears down the regenerative powers of the pancreas, thus explaining the unfavourable course of the disease. In pneumonia and other infectious diseases the pancreas readily regenerates after acute injury. The disturbed carbohydrate metabolism giving rise to abnormal fat or protein metabolites may be the cause of the high incidence of vascular disease in diabetic patients.

Primary Lung Tumours in Mice following the Cutaneous Application of Coal Tar (James B. Murphy, M.D., and Ernest Sturm, *Journal of Experimental Medicine*, November 1, 1925).—The external application of tar to a number of separated areas on the surface of mice, in such fashion that no single area is irritated sufficiently long to cause lesions of the skin, has resulted in a very high incidence of lung tumours. This incidence ranged from 60 per cent. in one experiment to 78·3 per cent. in another. Control mice from the same stock, but from three to six months older, and for that reason more liable to spontaneous lung tumours, failed to show a single instance of such growths. The tumours in the tar-painted animals occur as small white nodules, either single or multiple. They are typical epithelial neoplasms, identical histologically with those described by previous authors as occurring spontaneously in mice. Some possible factors in the causation of the tumours are briefly discussed.

Abstract.

SOME NOTES ON LATRINES AND HOOKWORM INCIDENCE ON AN ESTATE, AS DIAGNOSED BY THE CLAYTON-LANE CENTRIFUGE.

By Ronald Senior-White, F.E.S.,
(Malariologist, the Kepitigalla Rubber Estates, Ltd., Matale.)

The estate to which the following notes apply is in most respects typical of company-owned estates in the island of Ceylon. It seems probable, therefore, that the publication of figures showing the incidence of ankylostomiasis eight years after the Rockefeller Commission commenced work in the island will be of interest to those working on the disease.

Prior to the commencement of the Commission's campaign the estate, in common with practically every other such, provided no latrine accommodation for its labour force, who resorted for purposes of nature to the area around their lines, as was only too apparent to the nose when in the vicinity of the latter.

With commencement of work by the Rockefeller Commission, the provision of latrines was enforced by law. On the estate in question these were constructed over pits dug in laterite soil to the depth of sixteen feet, their sides being practically vertical and, after the first few feet—varying with top-soil depth in individual spots—of a hardness nearly comparable with a chalk pit in England. The buildings themselves were of tarred weather-boarding with corrugated iron roof, the squatting places being also of board, which was re-tarred at suitably frequent intervals. Each pit served four to six actual squatting places, the two sexes being accommodated on separate sides of a central wall. To each side a cement-floored ablution cubicle, draining into the pit, was provided and cemented inverts drains caught the roof-water and led it away from the pit. The original cost of such a latrine of four places, including digging the pit, averaged about Rs.250.

On this estate the latrines are all situated on a steeply-sloping hillside, and the pits nowhere struck subsoil water. They have remained absolutely dry throughout their existence. If such is struck, and the pit contains standing water, *Culex fatigans* will breed freely therein. To this is due the intolerable nuisance found in some of the wetter and more elevated districts of Ceylon, where mosquito nets are now absolutely essential, whereas, before the latrine ordinance, there was no need for such.

In practice it has been found that two squatting places for each sex for a set of ten line rooms (accommodating from twenty to twenty-five persons of over infantile age) is sufficient. One latrine of this size serving twice this number of rooms

---

[1] Abstract from the *Indian Medical Gazette*, December, 1925.

caused much fæcal pollution around the set of lines concerned until it was duplicated. Lids to the holes in the squatting places, self-closing by gravity, were originally provided. These proved unsatisfactory. The coolie usually fouls the squatting place around the hole, and when the lid falls back on the mess it is in no state to come into contact with the back of the next user.

Examination of the surface of semi-liquid mass of fæces in the pits by means of a torch has at times revealed a crawling mass of larvæ, mainly those of *Chrysomyia megacephala* Fb., adults of which have been noticed resting on vegetation around the latrines, but no fly nuisance has ever resulted. The explanation would seem to be that the larvæ must find dry loose earth for pupation, and such is not available above the mass on the hard, nearly vertical sides of the pit. The prepupal larvæ therefore, I think, perish. Oviposition must have been by eggs dropped into darkness for several feet. I do not think that any fly would descend into the pit itself, and on various torch examinations I have never noticed adults in the pits.

Naturally the pits must slowly fill up, however efficient bacterial action may be, but out of seven sets erected in 1917-18 it has only been necessary to close two for this reason up to the middle of 1925. One of these was a 6-place set, now replaced by two separate sets of smaller capacity, and the other served twenty rooms as mentioned above. It has also been duplicated. At the moment of writing one more set now requires replacement, the first set of four places serving only ten line rooms to fill up.

It is possible that the periodic rises of level, attributed to overuse, are not due to this, but to inhibition of bacterial action by the use of disinfectant. A little of the cresol compounds used in line sanitation must at times find its way into the pits, but I have never been able to correlate a bacterial upset with the emptying of a quantity of such solution into the affected pit, or the addition by sweepers of unauthorized substances, such as line rubbish containing fermentable vegetable matter, which is said to be a cause of unsatisfactory bacterial action, and I think the original explanation is correct. There is probably a definite ratio between the surface area of a pit and the quantity of fæces that can be successfully dealt with regularly, but I have never attempted to work this out.

Fæcal pollution of soil on this estate has been very carefully checked for the last seven years, until now it is ordinarily non-existent. Nevertheless, so ingrained in the Tamil coolie are his filthy habits that the least relaxation of vigilance always results in an outbreak of promiscuous defæcation. Punishment, or the fear of it, alone keeps the latrines in proper use. Such a result can only be achieved on an estate where the labour is under perfect control and is not otherwise discontented. On many estates the latrines exist more to comply with the law than for use.

Turning now to ankylostomiasis itself, the estate in question, in common with most of those in Ceylon, showed an infection rate of 98 per cent. to 99 per cent. by the simple smear method when originally surveyed. Being situate in the district in which the Rockefeller Campaign started operations, the original treatments were given without latrines being installed, and therefore for at least a year after reinfection must have occurred copiously. The rainfall on the estate is about 80 inches per annum, most of it in the North-East Monsoon, at which time of year the original treatments were carried on. No routine treatments were made for six years afterwards. Bad cases coming from India or other estates were treated soon after arrival by the dispenser, without microscopic diagnosis. In other words, " bad cases " would mean those showing a noticeable degree of anæmia and œdema—that is, very bad cases indeed.

The writer brought back with him from leave last year the then newly-demonstrated Clayton-Lane centrifuge for ankylostomiasis diagnosis, the first, he believes, to reach the island, and with it a routine examination of every coolie inhabitant of the estate was made. Owing to pressure of other work it was not found possible to carry out the complete Clayton-Lane technique for quantitative results. All that could be done was to take a lump of fæces approximately equal in bulk to 1 c.c. and emulsify it direct in saturated saline, the tube being then filled up till the meniscus stood just above its mouth, the cover-slip was applied and the whole centrifuged.

My laboratory boy and a sweeper under the supervision of the estate dispenser formed a gang just sufficient to keep myself at the microscope continuously occupied. The routine of operation was as follows:—

The sweeper opened the sample tins and removed and emulsified the material in about three-quarters of a tube of saline, standing each tube as completed in a test-tube rack. The dispenser meanwhile moved the opened tin and its labelled lid opposite the corresponding tube in the rack, and filled the latter up to the top. Then in the centrifuge bucket he added by a pipette the final amount of saline necessary to touch the cover-slip, and applied the same. The laboratory boy worked the centrifuge, carried slides to and from the microscope, and washed cover-slips. The sweeper washed the centrifuge tubes. Generally four slides, numbered consecutively to agree with holes in the test-tube rack, were used. The microscopist quoting the number of the slide under examination, the dispenser identified it with the patient from the label of the tin, and the result was entered. With this staff doing only quantitative diagnoses, it was found possible to do nearly sixty samples per hour after everyone had become used to their duties. Much longer has to be spent on a negative than on a positive slide.

The original treatment by the Rockefeller Commission was made with chenopodium oil—in the series now under discussion this was used for children and adults showing *Ascaris* infection, but the chief drug used was carbon tetrachloride. Coolies have no objections to the latter. In fact,

some negative patients asked for it when those still positive were under retreatment. It apparently has a somewhat alcoholic effect much appreciated by the coolie. No accidents with it have occurred here. The dosages were indicated by officers of the campaign as usual.

It will be observed that the numbers examined after the first treatment are less than those of the original examination. This is due to the omission from the former of negatives and those exempted from treatment for the usual conditions. In the fourth examination, made a year later, every inhabitant of the estate was again tested.

TABLE I.

	A. Apr. 3, 1924	B. Aug. 5, 1924	C. Sept. 18, 1924	D. June 11, 1925
No. examined	231	187	192	222
Ankylostoma positive ...	177	130	89	115
Ankylostoma negative...	54	57	103	107
Ascaris	8	30	41	54
Trichuris	3	22	24	42
Per cent. with *Ankylostoma*	77	69	46	52
Per cent. with *Ascaris*	3	16	21	24
Per cent. with *Trichuris*	1	12	13	19

A. No general treatment since 1917.
B. General treatment on July 3, 1924.
C. Retreatment of cases still positive on August 22, 1924, and September 4, 1924.
D. No general treatment during intervening period.

Analysis of Column D.

	Examined	Positive	Negative	Per cent. positive	
New coolies ...	29	21	8	72	All heavy
Old coolies ...	193	94	99	49[1]	40 per cent. of positives with 1-2 eggs only.
	222	115	107	52	

[1] Increase over column C due to inclusion of exempted coolies.

One very extraordinary point is brought about by the figures given above, viz., that apparently the more treatment that is done, the higher becomes the incidence of *Ascaris* and *Trichuris*. I am quite at a loss to account for this. The rise in the former after the first treatment, from 3 per cent. to 16 per cent., cannot represent fresh infection occurring in the intervening four months. Can it be that treatment irritates the worms into oviposition? Carbon tetrachloride is said to have no effect on *Ascaris*, and it is not known whether the ascaricidal fraction of the chenopodium oil was high. In any case, statistically, the position as regards *Ascaris* is worse at the end than at the commencement of treatment. It was obvious also, when doing the actual examinations, that ascariasis is largely a family infection. This must mean food contamination, and it would therefore appear that special attention to mothers of families who show ascariasis should be undertaken.

As in all labour forces there is a constant in and out movement of coolies, though it is smaller in the case of the estate under discussion than in many known to the writer. The figures of the last examination have therefore been subdivided to show new and old coolies separately, the latter being those who were present during the treatment of 1924. New coolies, in this instance, have none of them come direct from India, but all from neighbouring estates, and the incidence among these coolies, in spite of the fact that obviously infected cases were treated on arrival, is nearly double that of the old coolies of the estate, while in every case the amount of individual infection appeared higher. It is to be feared, therefore, that on most estates the ankylostomiasis incidence is still in the vicinity of 70 per cent., a fact which reveals how much has yet to be done before this disease is got under control.

TABLE II.

	Samoa. Infected Per cent.	Samoa. Reduction Per cent.	Ceylon. Infected Per cent.	Ceylon. Reduction Per cent.
Before treatment ...	97	—	77	—
After first treatment	59	38	69	8
After second treatment	37	22	46	23

Comparing the foregoing table with the figures recently published from Samoa, using the same technique (Hopkins, 1925) we get:—

Even allowing that the original reduction in the Ceylon series had been from about 98 per cent., and that, if the first treatment of 1924 had been on virgin ground as in Samoa, the reduction might well have been from that figure down to 69 per cent., we still find that there is less reduction for first treatment in Ceylon than in Samoa. The reductions for the second treatment are practically identical in the two islands, and at the end of it both sets of patients were left with a large amount of residual infection. Probably little of this was economically important to the patients themselves—and if everywhere proper usage of latrines was in force would have comparatively little importance, but there is no word of the use of latrines in the Samoa paper, and we know that they are very ineffectively used in Ceylon, hence these half-cured cases may not only get more heavily infected themselves, but are still liable to act as disseminators of the disease. The first is likely to be of more occurrence with many of those treated here, for at the final examination 38 of the 94 positive among the old coolies, or 40 per cent., showed only one or two eggs in the film made from approximately 1 c.c. of stool. These would count as negative "cured" under any technique less delicate than that of Clayton-Lane. This is simple and sure, and even for routine campaign diagnosis an immense improvement on any of the pre-existing ones. I would like, however, to confirm Hopkins' remarks about the apparatus. The plating and paint is rapidly and badly attacked by the salt solution, though in my case the aluminium arms have not been affected. The handle also should be of stronger construction for unskilled use. With advantage also the arms might be permanently numbered so as to render tube-tin-slide identification simpler, but these points are all minor blemishes such as invariably show themselves in any new pattern of apparatus, and will doubtless be rectified in later manufacture.

THE "PURU" OF MALAYA: ITS TREATMENT AND ERADICATION.[1]

By A. VISWALINGAM, L.M.S. (Singapore),
Assistant Medical Officer, F.M.S. Medical Service, Kuala Lumpur.

INTRODUCTION.

OF the many diseases that are prevalent in Malaya, none is of more interest and importance to the native population than the disease called "Puru." Although it is not in itself a fatal disease, it has wrought havoc among the Malay people. By impoverishing general health it paves the way for other diseases and thus indirectly raises the sickness and mortality rates.

Its effects on the community are far-reaching. It is a great hindrance to the progress of the race and the material development of the country. Many of the unfortunate individuals stricken with the disease are disabled from work, or at least from performing their work efficiently. Others, as a result of deformity, prove a burden on the community.

THE PEOPLE AND THEIR HABITS.

The Malay lives a simple life. His wants are few, and Nature is so bountiful that these are readily supplied with the expenditure of little energy. His chief occupation is paddy cultivation and fishing. He bathes in, and drinks from, the many streams and rivers that abound all over the country. Fruits are abundant and varied, but the "durian" is the favourite. His dress is simple, consisting of a piece of cloth which he wears round the waist and which reaches to the knees, and of another with which he covers the upper part of the body. His arms and legs are thus left bare, and he goes about with bare feet. He lives in thatched huts with bamboo walls and flooring raised a few feet above the ground. The ground underneath is invariably damp, partly due to the heavy rains, and partly to the refuse water from the kitchen which finds its way below through the floor.

GEOGRAPHICAL DISTRIBUTION.

Puru has existed in Malaya for very many years, affecting chiefly the aborigines and others of the indigenous population; the former are the Sakais, the latter the Malays and Javanese. It is also prevalent in the various East Indian and Pacific Islands and in Ceylon. In Ceylon it is called the "Parangi," from the belief that it was introduced by the Portuguese (*Ferangi*), in Africa "Yaws," or "*frambœsia*," from its resemblance to the raspberry, in Fiji "Coko," and "Buba" in the Pacific Islands.

DEFINITION.

Puru may be defined as a specific contagious disease, with an uncertain period of incubation, and characterized by a series of crops of characteristic skin eruptions. It runs a definite course, attacking all persons irrespective of age or sex.

CAUSE.

In all countries where yaws is prevalent the consumption of various articles of food is said to be the cause of the disease. In Malaya, certain kinds of salt fish and a particular rice are blamed. Malays also believe that the eating of durian fruit aggravates the disease, and that fresh crops of the eruptions occur when this fruit is in season. In Ceylon the eating of "kurakkan" (ragi) and some variety of fish is said to bring on the disease. A cold and humid atmosphere is thought to aggravate symptoms. Be this as it may, medical science has proved that the cause of the disease is the presence of a microbe, the *Treponema pertenue*, a minute organism measuring from 0·000204 to 0·000278 in. in length.

MODE OF SPREAD.

The microbe enters the body through trivial wounds or sores on exposed parts of the body, such as result from scratches, leech-bites, contact with "machang" or "durian" blossoms, from itch mites, &c. The infected sore is slow to heal and becomes indolent, developing ultimately into the typical yaw. Personal contact, or contact with infected clothing or household utensils and other implements of everyday use, serves to spread the disease.

The frequency of the disease in "kampongs," and its rarity in towns, seem to show that it is one of the diseases associated with filth and general insanitary conditions. The house-fly possibly plays an active part in dissemination. Open ulcers are often found covered with flies, and it is reasonable to suppose that the germs are spread from the diseased to healthy persons in this way.

In a series of hundreds of cases that came under the writer's observation the avenues of invasion were parts exposed to injury, such as feet, legs, back of the elbows, arms, face and front of the knees.

The relative frequency of infection in the upper and lower limbs was 1 : 2. In children the frequency of the primary sore about the mouth and face points to foods or food utensils as possible vehicles of infection, but flies hovering about the face of a child may be the vectors. In Ceylon it was a practice to feed a child with food which had been previously contaminated by an infected individual with a view to causing a mild infection and thereby induce immunity.

INCUBATION.

Once in the body the germs multiply, but symptoms are not produced until they have attained enormous numbers. The time taken by them to multiply to such an extent as to cause symptoms is called the "incubation period." This varies from a few weeks to months.

INCIDENCE AND RACE.

It is believed that among the Malays of the Malay States, 60 persons out of 100 either have or have had puru. Chinese and Indians also contract the disease, especially in the interior of the country, where it is most prevalent.

[1] Published for The Committee for Public Health Education of the Federated Malay States, by John Bale, Sons & Danielsson, Ltd., 83-91, Great Titchfield Street, Oxford Street, London, W.1.

Age.

All ages are affected, but the liability to infection is greater in infancy and childhood. Of about 1,500 cases observed, the youngest was three months old and the oldest 90 years. The great majority contract the disease in childhood.

Sex.

Both sexes are equally liable to infection, but the ratio in the cases observed was three males to one female. This is due purely to the greater chances of injury and exposure to infection in the male child.

Transmission.

The disease is not inherited. Not infrequently a nursing mother gets infected by suckling a child with sores about its mouth, and who contracted the disease from another child while playing or taking food with it. It is not as a rule transmitted by sexual intercourse, as is the case with syphilis, but it is conceivable that the disease may be so contracted in the presence of lesions.

Signs and Symptoms.

The signs and symptoms of the disease are usually divisible into three stages, viz., the first stage or stage of onset; the second stage, the stage of evolution; and the third stage, the stage of decline. Before the onset of the disease the individual may have nothing more than a feeling of lassitude, slight fever and malaise.

First Stage.—The initial lesion or sore that develops at the site of inoculation is usually single and is called by the Malays *ibu puru* (mother of puru). It appears to arise from the deep tissues of the skin and push its way through to form what is termed a *granuloma*. This varies in size and shape. The distinctive characteristic of puru may be described as an eruption of one or more small papules, which increase in size and secrete a viscid yellowish discharge which dries and forms a crust or scab. On removing the scab a raw surface is exposed, which bleeds readily and looks not unlike a "rambutan" in colour and appearance. This sore may heal up, leaving hardly any scar, or it may, on the other hand, take a chronic course and leave a permanent scar. The initial sore may last as long as six to twenty-four months, with or without evidence of the second stage.

Second Stage.—This consists of eruptions which appear in successive crops for several years. The typical eruptions consist of *granulomata*, similar to the initial sore, varying in size from a pin's head to an areca-nut and are termed by the Malays "anak puru," i.e., "the child of the yaws." These eruptions, which may be accompanied by an irregular fever of short duration, appear some weeks or months after the parent sore. They may co-exist with, or appear after, the parent sore has healed up. They may be discrete, or confluent, occur in any part of the body, or affect its entire surface. In infants and children the confluent type is most common. The tendency towards the discrete type increases as age advances. The backs and fronts of the arms and legs are equally affected. The eruptions may be of various sizes and shapes, they may be round, oval, or ring-shaped or irregular, and are given corresponding names by the Malays, viz., "puru sipit," "puru mata-kerbau," "puru tapak-anging," "puru parang," "puru bubol," "puru sipit mulut," "puru durian," "puru bunga," "kedal," &c.

Wart-like eruptions on the palms of the hands and soles of the feet are said to recur every year with regularity during the "durian" season. A most common type of lesion is the pitted sole. In it the skin of the sole appears as if it had been perforated by a pin. Another common foot lesion is the thickened sole, in which the skin shows areas of thickening; when these protrude above the surface and crack, the enormously thickened skin appears as if split through by some protruding mass. In one case the whole skin on the back was covered with minute eruptions resembling the rind of the jak fruit. The eruptions run their course and heal up, or as a result of infection by other organisms, ulceration may set in involving large areas of skin. The bones may become affected and thickening result. The ends of the bones of the arms and legs may become involved and deformity result.

In one case, that of a girl, the bones of the arms, legs, fingers and toes were enormously thickened and necrosed. In some cases the joints are swollen and tender, in others pain only is complained of. In rare cases the bones of the feet are affected so as to produce a condition resembling "madura foot."

The Third Stage.—This may set in during or after the second stage. It generally consists of an affection of the skin in the palms and soles and is called by the Malays "kedal." In slighter cases the skin presents a condition of exfoliative dermatitis, with superficial cracks and fissures. In severe cases the skin is thickened, cracked and fissured, and in some there is ulceration, making it impossible for the patient to walk or grasp anything. This stage may persist for years with exacerbations. Together with this, or after the exfoliative condition passes, the skin may lose its pigment and presents a condition almost resembling *leucoderma*. It regains its normal appearance after treatment with *novarsenobillon*. In neglected cases and enfeebled constitutions the eruptions of the second stage are followed by extensive ulcerations leading to the loss of fingers and toes, and to permanent contractions and deformities.

Diagnosis.

This is generally easy in endemic areas. The typical *granulomata* of the first and second stages could hardly be mistaken for any other disease, but in cases which deviate from the typical, one must be guided by the history, age, race, &c. With careful observation and diligent inquiry, the seat of the primary sore can be ascertained. In cases showing the manifestations of the third stage there is likely to be difficulty, but it can be overcome by inquiry and search for evidence of past lesions, scars, deformities, &c.

Prognosis.

This is very favourable, as the disease can be arrested in all its stages. If treatment is given as soon as the disease manifests itself, there is great likelihood of prompt cure and prevention of the further ill-effects that result from this disease.

TREATMENT.

Although puru has existed for centuries its treatment was unsatisfactory until a few years ago, when Professor Ehrlich synthetized a compound of arsenic known as *salvarsan*, and a later modification, *neosalvarsan*. In *neosalvarsan* and *novarsenobillon* (allied preparations of arsenic) we have remedies *par excellence* for puru. Since Ehrlich's discovery hundreds and thousands of people who were dragging on a miserable existence have been cured. In the Malay States systematic treatment with *novarsenobillon* on a large scale was begun in Kuala Kangsar by the writer about five years ago, where hundreds of people from various parts of Perak were cured or benefited. The simplicity of the method of treatment, and above all its efficacy, has enhanced the value of scientific medicine in the eyes of the Malays and created a keen desire for the cure of yaws. Government has now placed this cure within the reach of every person throughout the States by sending out medical officers to visit the people in their "kampongs," where centres are arranged and injections are given free. The affected individual has only to visit either the local centre or the nearest hospital, where he will be promptly treated. He should attend until he is declared cured by the doctor. Besides medical treatment, due regard must be paid to the diet and cleanliness of the patient and his surroundings. The administration of such a potent drug as novarsenobillon should not be undertaken lightly. Its action varies with each individual. Some patients feel sick almost before leaving the table, whereas others do not experience the slightest discomfort. The immediate effects may be a feeling of nausea, vomiting, occasionally fever (99-102° F.), congestion of the face, giddiness and, rarely, collapse with profuse perspiration. These symptoms may be transient and pass off quickly.

Toxic symptoms seldom develop earlier than five to seven days.

Care must be taken in the case of women not to exceed 0·3 grm. of the drug at one time, and in the case of men not to exceed 0·45 grm. It should not be employed in patients who had been under prolonged treatment with *arsenic* or *antimony* by the mouth. The writer has seen at least one such case resulting in peripheral neuritis followed by gangrene of the lower limbs.

PREVENTION.

This is a matter of hygiene and rural sanitation. To avoid contracting the disease attention must be paid to all wounds and sores, however trivial they may be, and to have them dressed so that no flies might get on to them. All rubbish which helps to breed flies must be burnt and the dwelling-houses and their surroundings kept clean. Personal and domestic cleanliness must be the aim of every individual. Every person suffering from puru, as well as his clothing, bedding, &c., must be kept apart and away from flies.

ERADICATION.

Eradication of puru from a country where it has existed for centuries, and parts of which are yet to be opened up, is no small task. But any labour and money spent on eradicating this disease would be justified by results. If the following measures are taken, with the intelligent co-operation of people who realize the baneful effects of the disease, we may with confidence hope to see the eradication of puru from the Malay States.

(1) Every individual who suffers or has suffered from the disease must be examined, and if necessary undergo the treatment. Every individual so cured is one less centre of infection.

(2) His family, relations and servants should likewise be examined.

(3) He must tell those who are not familiar with the disease about its symptoms and the ease with which it can be cured.

(4) We must instruct his household to prevent the breeding of flies by maintaining domestic and personal cleanliness.

(5) Every individual who has puru must be looked upon as a menace to the health and advancement of the community, and therefore isolated from the healthy until free from risk of spreading infection.

(6) People must be warned that new arrivals in the "kampong" showing active signs of disease must be kept isolated, otherwise the whole "kampong" may become infected.

(7) Healthy individuals should never eat from the plate from which a diseased individual may have eaten, or share food from his hands. All social dealings with infected people must be stopped.

(8) A census of all persons suffering from yaws should be taken, and all such persons required to attend for treatment.

(9) Lessons on elementary and personal hygiene, with special reference to the household fly as a disease carrier, should be included in the school curriculum, and lectures given to the adults when opportunity offers.

CONCLUSION.

Although puru has existed in almost all the tropical and subtropical regions of the world for several centuries, systematic attempts at eradication commenced only a few years ago. Many observers have recognized the disease as an entity, while others confound it with syphilis, lupus, gangosa, leprosy and skin diseases. This is perhaps due to insufficient acquaintance with the varied symptomatology of the disease. This short account of puru is meant for those who may have to deal with the disease in Malaya, and also for the information of the general public, so that by intelligent understanding and co-operation, prevention and cure may eradicate this disease from the country.

Current Literature.

THE AMERICAN JOURNAL OF TROPICAL MEDICINE. Vol. V, No. 6, November, 1925.

General Report on the Yellow Fever Campaign in Colombia, May 1923, to December 31, 1924 (Henry Hanson).—Until the outbreak of yellow fever at Bucaramanga in March, 1923, it was believed that the disease did not exist in Colombia. The campaign was carried out here and at several

other places of importance and principal seaports. The total number of recorded house visits of the general campaign is 910,845. In the course of these inspections houses were found breeding *Ædes ægypti* mosquitoes in 69,690 instances. The distribution of 364,926 fishes as larvæ consumers is recorded. The use of fish in Colombia was not followed by the striking beneficial results expected, on account of the fishes being delicate, also because the people would not co-operate in the care of the fishes distributed. In places where proper attention was given to the fish no larvæ were found. While it is believed that there is now no yellow fever in Colombia, the disease would probably spread extensively were it reintroduced into the country on account of the generally high mosquito index, and for this reason serious attention should be given to the control of *A. ægypti*.

Prevalence of the Yellow Fever Mosquito, Ædes ægypti (Linn.), in Colombia (L. H. Dunn and H. Hanson).—During the recent campaign against yellow fever in Colombia mosquito control measures were carried on at the more important centres and main key points of travel. Many other towns and villages in various parts of the country were also visited and inspected. This gave quite a complete survey of the distribution and prevalence of *A. ægypti* throughout the Republic. A total of fifty-six places were investigated for mosquito breeding, at eighteen of which control measures were established, preliminary inspections only being carried on at the other thirty-eight.

Mosquito breeding was found at forty-six of the fifty-six places inspected. The highest house index was 96 per cent. at Banco. The lowest was 6 per cent. at Buenaventura. However, at this latter place control measures were being continued from a previous campaign. The lowest index found where no control measures had been carried on preceding the inspection reported was 13 per cent. at Florida. The house indices of forty-five of these places with breeding may be roughly grouped as follows: eight were less than 25 per cent., nine between 25 and 50 per cent., eighteen between 50 and 75 per cent., and ten were more than 75 per cent. Four places, Banco, Villamizar, Cucuta and Quibdo, gave indices of more than 90 per cent. No index was obtained at Aracataca. An accompanying map of Colombia illustrates the locations of the various places where these investigations were carried on.

Geographical Distribution of the Serologic Groups of Brucella melitensis (Alice C. Evans).—The results of this study show that the various serological groups of *B. melitensis* are not limited to particular species of host animals. The prevailing idea that the so-called "*Bacillus abortus*" is a bovine infection and that the so-called "*Micrococcus melitensis*" in a human and goat infection should be revised. The *abortus* variety is characteristically a bovine infection, for twenty of the twenty-three bovine strains fell into this group. The *abortus* variety is also the variety which infects hogs most frequently in America, for eight of the nine porcine strains fell into this group. It is now an uncommon agent of human infection, for five of the twenty-three human strains fell into the *abortus* group. The table shows that the *melitensis* A strains in this collection came from human, caprine, bovine and equine sources. Since the two varieties of the organism cause the clinically typical Malta fever in man, and both cause the same kind of disease in animals, there are practical reasons as well as scientific for considering the entire group as a single species.

Suspected Yaws in Costa Rica (Solon Nunez).—In the zone of Coto and Golfo Dulce (boundary zone between Costa Rica and Panama) there exists a dermatosis which is contagious, with tendency towards an epidemic character. The clinical and serological characters and the influence of the arsenical treatment leads one to believe that it is a spirochætosis. The form of the papules, their colour and their mode of evolution make one think of yaws. Failure to find the spirochæte was probably due to the advanced state of the disease. The cases of yaws described, if correctly diagnosed, appear to be the first to be reported from Costa Rica.

Experimental Immunity in Syphilis and Yaws (Henry J. Nichols).—The author reviews the work of recent investigators and gives an account of his own experiments which clearly suggest that yaws protects against syphilis. The recent demonstration of a true immunity in syphilis throws new light on this question. Experimentally, a partial immunity against syphilis can be demonstrated in rabbits which have been infected a long time with yaws and cured by arsphenamin. The subject of strains must be taken into account, both in yaws and syphilis.

FINAL REPORT ON THE TREATMENT OF TRYPANOSOMIASIS IN UGANDA.

By C. H. MARSHALL, M.B., B.S.(Lond.), F.R.C.S.(Edin.),
Senior Medical Officer, Uganda,

AND

S. M. VASSALLO, M.D., D.T.M.& H.,
Surgical Specialist, Zanzibar.

THE treatment of trypanosomiasis by means of rathecal salvarsanized serum having recently en far less successful than was previously ported, we felt it incumbent upon us to give blicity to that fact, and did so by means of a ter in the *British Medical Journal* in June, 1924. We would wish, however, to place on record the ults of our experiments up to date, since even e records of failures may not be without their lue, and also as, owing to the exigencies of the rvice to which we belong, we are no longer in a sition to continue our investigations.

The methods of treatment which we consider as ving failed were carried out in the Madi country. the Nile district, during April and May, 1922, ong natives far more primitive and uncivilized an those round Mbale. As indicated in our mmunication to the *British Medical Journal* of bruary 10, 1923, they were planned to investigate e suggestion, offered by Dr. Shaw Mackenzie, at the results obtained by serum treatment might e due to fat-splitting by the autogenous serum, d also to attempt to perfect a single treatment ith simple technique which would enable the tient to resume his normal life after a few days, d so avoid the prolonged courses of injections ich necessitate the removal of the patient from village and friends and his confinement in some eping sickness camp or hospital.

Before commencing treatment of any kind we deavoured to make some classification of our ses according to the different stages which the sease had reached, to facilitate a correct evaluan of any results which might be obtained.

The necessity for some such system is apparent. r instance, Broden and Rodhain, in the Congo. ite that good results may be obtained from the travenous injection of salvarsan, but they insist at it is only of benefit in those cases where micropical examination of the cerebro-spinal fluid ows that invasion of the spinal canal has not curred.

The invasion of the central nervous system may presumed in the later stages from the clinical ns, and in this connection Manson (7th edition, ge 125) definitely states, " Later there may occur rillary twitchings of the muscles, especially of tongue, and tremor of the hands, more rarely of legs, indicating a definite implication of the otor centres."

In the early stages of the disease the question is ore difficult, since, while theoretically the absence parasites or increased cell contents contradicates an infection of the central nervous system, this may not be a matter of actual fact, since a few trypanosomes in the cerebro-spinal fluid may escape detection.

The classification we adopted was as follows:—

Class A.—The onset of infection. Characterized by the presence of trypanosomes in the blood, but without glandular enlargement. The patient has constantly recurring attacks of pyrexia, associated with great malaise, pains in the head and back. Skin rashes may be present, but there are no nervous symptoms.

Class B1 (subacute).—The spread of infection from the blood to the lymphatic system.

The cervical chain of glands is enlarged, individual glands varying in size from a pea to a cherry; the larger ones are usually " typical " on palpation, i.e., they feel like a ripe plum. Trypanosomes are present in the gland juice. There are no nervous symptoms, knee-jerks are normal, and there are no tremors of the tongue or fingers.

The morning axillary temperature is from 99° F. to 100° F. At this stage there is no clinical reason for supposing that the infection has reached the cerebro-spinal canal. In this connection it may be noted that Dr. R. G. Griffin (D.M.O., Uganda) has reported enlarged axillary glands, containing trypanosomes, in many cases where the cervical glands were not palpable. (*Trans. Roy. Soc. Trop. Med. and Hygiene*, Vol. xvii, Nos. 1 and 2, March and May, 1923).

Class B2 (early chronic).—The onset of nervous symptoms. The lymphatic glands may reach the size of a large damson, and microscopical examination of the gland juice often shows two or three trypanosomes in each field. The mental functions are much impaired. Tremors of the tongues and fingers are present and the knee-jerks are increased. The patient is often emaciated and suffers pains in various parts of the body, a dull headache being a prominent symptom. The morning axillary temperature is between 98° F. and 99° F.

Class B3 (late chronic).—The stage of incipient sleeping sickness. The patient is emaciated and has a harsh dry skin, while the lymphatic glands become sclerosed and smaller. (At times a bloated appearance is presented, but in these cases secondary infections and infestations may play a great part. ankylostomiasis probably ranking pre-eminent.) The male is usually impotent. The knee-jerks are increased and ankle-clonus is usually present and Romberg's sign is well developed. There is loss of strength and the gait is shuffling and unsteady. There is a marked somnolence and mental apathy and the temperature is usually subnormal.

Class C.—This stage represents the condition of true sleeping sickness. The patient is unable to stand, and has marked cerebral nervous symptoms, often being only semi-conscious. There is marked wasting and the knee-jerks may be absent, although Babinski's sign is usually obtained.

It is of course impossible to draw any hard and fast lines between the different stages of the disease, and a patient in any class may well be lacking in one or more of the signs described.

In other words, classification must be based upon the clinical picture as a whole.

Also, it is difficult to state definitely the length of time associated with the various stages suggested. The state described under " A " will only be diagnosed in those whose blood is examined in the first instance for the presence of *Spirilla* or the parasites of malaria to account for the raised temperature.

Possibly this stage lasts a considerable time, during which, we would suggest, the infection may die out naturally, the disease never having been recognized. This suggestion is supported by several observers reporting cases of trypanosomiasis which had no treatment at all and yet lived for prolonged periods.

Nattan-Larrier (French Congo, 1908) reports three Europeans living 17 months to three years, and Todd (1911) mentions five cases, four of whom were " alive and well " two to three years after diagnosis. None of these eight cases had any form of treatment.

On the other hand, Dr. G. C. Low and Dr. E. O'Driscoll report a case of trypanosomiasis from Nigeria in whose cerebro-spinal fluid trypanosomes were found five months after infection, indicating that what we have termed the B2 stage had then been reached. (*Transactions of the Royal Society of Tropical Medicine and Hygiene*, Vol. xv, No. 5, Nov. 17, 1921.)

We suggest, however, that from the B2 stage onwards the disease is beyond the possibility of a natural cure and gradually progresses, though to state exactly what stage has been reached is a purely arbitrary matter. For the " C " class patient the expectation of life is very short.

Except in the case of the " A " class patient (onset of infection, no gland enlargement), we believe that trypanosomes are rare in the peripheral blood-streams. We examined 30 untreated cases belonging to classes other than " A " without finding a single trypanosome in the blood.

In addition we sent 126 blood-films to Dr. Mary Martin, the assistant bacteriologist, Uganda, who, after exhaustive search, reported the presence of trypanosomes in 23 slides only. The suggestion that the visible presence of trypanosomes in the blood-stream is rare is supported by MacFie and Gallagher (1914), who report that no parasites were found in the peripheral circulation of 222 cases of trypanosomiasis examined in the Eket district of Nigeria.

This point is somewhat emphasized as it would appear to be of considerable importance as regards the spread of infection; for if trypanosomes are only found in the blood of early cases it may be presumed that this is the class of patient mainly responsible for infecting the fly, and consequently either patients of " A " class are much more numerous than is usually supposed, or else the number of human hosts necessary to spread the infection is very small.

It is, of course, realized that Miss Robertson found that the infectivity of the disease when transmitted by *Glossina* increased during the time that the less numerous short forms of trypanosomes we present, and diminished when the blood showed large number of parasites of the long type. (Mi Robertson, *Reports on the Sleeping Sickness Co mission of the Royal Society*, No. xiii.) This, ho ever, does not appear to afford an explanation view of the apparent absence of the trypanosom from the circulation of so many cases.

In the cases of treatment that we record, no " A or " C " cases have been included.

The treatment in Madi was based on the p sumption, itself based on our experience in Mba that the best results hitherto obtained have be those from intrathecal salvarsanized serum, and endeavoured to find answers to the follow questions:—

(1) Except in the very early stages (" A " cl patients) is a single intravenous injection of arsenical preparation sufficient to cure the infectio

(2) If serum is essential does it give as g results if the injection is intramuscular as when i intrathecal?

(3) Must such a serum be autogenous?

We also tried the effects of two drugs suggest by Dr. Shaw Mackenzie, viz., (*a*) pure curd so and (*b*) copper alanine.

In all 214 cases were treated by the vari methods indicated in our previous report, Febru 10, 1923, and are shown in the following table:

TABLE I.

(*Showing method of treatment adopted and number of case treated.*)

Treatment employed	Class of Disease B 1	B 2	B 3	T
1. Intrathecal serum following intravenous arsenic	7 ...	28 ...	13	
2. Intrathecal serum following intravenous " B "	1 ...	1 ...	2	
3. Intrathecal serum (as in 1 above) followed by intramuscular inactivated serum	2 ...	4 ...	1	
4. Intrathecal serum without intravenous injection	2 ...	1 ...	3	
5. Intramuscular serum following intravenous arsenic	11 ...	20 ...	9	
6. Intramuscular serum without intravenous injection	5 ...	23 ...	6	
7. As in 6 above, but followed by intramuscular inactivated serum	3 ...	2 ...	1	
8. Intravenous arsenic only... ...	4 ...	7 ...	3	
9. Intravenous " B " only	4 ...	6 ...	2	
10. Intravenous " A " only	2 ...	6 ...	4	
11. Intramuscular " A " only ...	4 ...	6 ...	1	
12. Intrathecal heterologous serum	2 ...	4 ...	1	
13. Intramuscular heterologous serum	1 ...	3 ...	0	
14. Intravenous arsenic followed by intravenous " A "	2 ...	1 ...	0	
15. Intrathecal heterologous serum, without intravenous injection ...	0 ...	1 ...	0	
16. Intramuscular salvarsanized serum (as in 5 above) followed by inactivated serum	1 ...	3 ...	2	
17. Intramuscular serum plus autogenous cerebro-spinal fluid ..	0 ...	1 ...	0	
	51 ...	117 ...	47	

In addition 45 patients were not treated but kept as contr

It is not necessary to give the results in gr detail, as except where the treatment compris intravenous arsenical medication, all cases sho

00 per cent. positive results when re-examined fter 12 months.

Cases which had received intravenous arsenic as art of the method of treatment gave the following esults after 12 months:—

TABLE II.

(1) Intravenous arsenic alone. (Treatment, 8.)

	B 1 Per cent.	B 2 Per cent.	B 3 Per cent.
ositive or dead	50 ...	43 ...	100
ive and well	50 ...	57 ...	0

(2) Intramuscular salvarsanized serum. (Treatment, 5.)

	B 1 Per cent.	B 2 Per cent.	B 3 Per cent.
ositive or dead	50 ...	60 ...	63
ive and well	33 ...	30 ...	27
ot seen	16 ...	10 ...	10

(3) Intrathecal salvarsanized serum. (Treatment, 1.)

	B 1 Per cent.	B 2 Per cent.	B 3 Per cent.
ositive or dead	33·3 ...	28 ...	35
ive and well	66·6 ...	56 ...	50
ot traced	— ...	15 ...	14

After 22 months only 25 cases of all the 214 atients treated by various methods were found to e alive and well, but it is interesting to note that f these 25 cases no less than 20 had been treated y intrathecal serum.

As these figures were anything but satisfactory, e felt called upon to indite our letter to the *British Medical Journal* previously referred to, stating that ntrathecal salvarsanized serum had not given the esults we hoped for, and had not furnished any eplies to the questions we set ourselves to answer.

On the other hand, the patients treated in the Mbale district were re-examined in September, 924, and the following table shows the results btained:—

TABLE III.

No. of case	Months since treatment commenced	Remarks
2 ...	72 ...	Well[1]
4 ...	68 ...	Well
7 ...	58 ...	Well
8 ...	60 ...	Well

29 ...	52½ ...	Well
30 ...	50½ ...	Died August 31, 1924
32 ...	51½ ...	Well
46 ...	48½ ...	Well
55 ...	45½ ...	Well
60 ...	42 ...	Well
61 ...	42 ...	Well

Case 26 treated 52½ months ago, was not seen but is reported alive and well.)

[1] "Well" indicates that the patients showed no clinical igns and gland puncture and blood examination proved egative.

That is to say, of the 27 cases reported up to February 31, 1922 (*vide British Medical Journal*, February 10, 1923, and examined again in September, 1924 (S.M.V.), five had died and one case relapsed, while 21 remain alive and well and showing no signs of trypanosome infection on clinical and microscopical examination, although from 3½ to 6 years have elapsed since they were found to be infected, and they have received no treatment other than the one intrathecal injection of salvarsanized serum.

The worst construction has been placed on these figures, as in one case death is known to have been due to disease other than trypanosomiasis, and in no case was death proved to have been due to this cause.

Further, some patients were liable to re-infection, and one case was noted for especially careful watching as he was actually working in the sleeping sickness area.

Considering the very marked difference in the success of similar treatment in these two districts, we naturally endeavoured to find some explanation as to why better results were obtained in the Mbale than in the Madi area.

The first suggestion which occurred to us was that the trypanosome was more virulent in Madi than in Mbale, but this does not appear to be so, for the following reasons:—

(1) A number of cases of trypanosomiasis at Mbale were treated by methods other than by intrathecal serum.

TABLE IV.

No. of case		
7	Relapsed	
14	Well	
28	Well	All early cases
31	Well	
34	Dead	
35	Relapsed	
36	Not traced	
56	Died	
57	Not traced	
58	Well	
62	Relapsed	
63	Relapsed	
64	Died	
65	Died	
66	Died	
67	Died	
68	Relapsed	

Out of seventeen cases four are found to be alive and well, eleven are either dead or show trypanosome infection, and two cannot be traced.

(2) Rats subinoculated by one of us (S.M.V.) from the blood of patients in Madi, showing rapid progress in the disease, ran a normal course of infection, parasites not being found in their blood for 9-12 days, and the rats remaining alive, comparatively well, until they were destroyed three weeks later, during the whole of which time their blood continued to show trypanosomes.

We would suggest, however, that two factors may be of paramount importance.

(i) The nature of the fly infestation of the two areas.

In the Mbale district the source of the trypano-

some infection is from the shores of the Mpologoma river, part of which has been thoroughly cleaned and is constantly supervized by a European sleeping sickness inspector, while other parts have, for administrative reasons, been left alone. As a result, many cases of trypanosomiasis after treatment have returned to live in a fly-free area, although others have been exposed to the risk of re-infection.

In Madi, on the other hand, the whole country is remarkably honeycombed with small streams, all potential and, in the great majority of cases, actual harbourers of *Glossina palpalis* and *Glossina morsitans*, which abound over the whole district, and consequently there may be a constant infection of sound individuals combined with a continual re-infection of those already suffering from the disease. The conditions closely resemble those described by Hodges as existing in the Lake Victoria Nyanza area during the great epidemic of 1906-1909, except that the actual dwelling places are out of reach of fly.

(ii) The second factor is the widespread prevalence of infections by debilitating diseases, such as yaws, syphilis, ulcers, guinea-worm, and especially intestinal parasites, in the Madi district.

One of us (S.M.V.) examined the stools of 35 unselected natives, with the results shown in the following table, these figures being the more striking when it is noted that the stools which were found negative had been brought on a leaf for examination and were several hours old and dried up:—

TABLE V.

Ankylostomes present in	63	per cent.	of	all cases	examined.
Ascaris	,, 26	,,	,,	,,	
Tænia	,, 14	,,	,,	,,	
Trichostrongylus	,, 11	,,	,,	,,	
S. mansoni	,, 6	,,	,,	,,	

The fact that only a limited number of stools and fresh preparations of blood were examined in the field was due to the exigencies of the tour, and while such limited numbers cannot be conclusive, the results obtained are very suggestive.

We therefore suggest that the marked mortality of the disease in the Madi, as compared to the Mbale district, is due to:—

(1) A repeated superimposed infection from continuous exposure in fly-infested areas.

(2) The possible debilitating influence of intestinal parasites, of which the ankylostome is of primary importance.

Finally, since we still believe that, apart from such conditions as exist in Madi and possibly elsewhere, intrathecal serum has given the best results as regards treatment, we endeavoured to obtain a true comparison of its effects by treating a series of cases at Mbale with (1) Bayer "205," and (2) tryparsamide:—

	B 1	B 2	B 3	
Bayer "205":—				
Alive and well ...	3 ...	3 ...	1 ...	7
Relapsed ...	1 ...	— ...	4[1] ...	5
Tryparsamide:—				
Alive and well ...	7 ...	4 ...	2 ...	13
Relapsed ...	— ...	1 ...	3 ...	4
Not traced ...	— ...	1 ...	1 ...	—

[1] Two cases treated by Bayer "205" were subsequently found still to show trypanosomes and were retreated by tryparsamide, when the parasites disappeared.

From the limited number of cases and the short time which has elapsed since treatment was commenced no definite conclusions can be drawn, but it would appear that tryparsamide gives considerably better results than Bayer "205," and that neither shows any superiority over intrathecal serum.

Recent teaching in the Edinburgh V.D. clinic traces the value of tryparsamide in parasyphilitic cerebro-spinal lesions to its passage into the cerebro-spinal fluid. This, in our opinion, explains its superior therapeutic action over the other drugs and would support our contention that in the more advanced stages of trypanosomiasis intrathecal medication is essential.

The principle involved is identical except that by the injection of intrathecal serum we hoped to obtain sterilization of the cerebro-spinal fluid through the introduction of "antibodies" and complement.

As we have previously pointed out, any treatment involving a series of injections over a considerable period is contra-indicated in dealing with natives.

Several patients who were treated with Bayer "205" or tryparsamide ran away as soon as their condition improved, without completing the course, and these could not be included in the results detailed above.

Also no comparison can be made between the treatment of European patients in England and the treatment of natives on a large scale in Africa, since the native, unless he is seriously ill, will not stay in hospital or continue treatment once he feels better.

Patients of Class "A" are therefore hardly ever diagnosed among natives, while in the majority of Europeans the disease is discovered in its early stages. This is a factor which can only be eliminated by the education of the native, and such education can only be effected by an efficient medical staff and abundant hospital facilities for all natives who present themselves for treatment of any form of disease.

In concluding this report of our observations and experiments in connection with the treatment of trypanosomiasis, we contend that in describing the results of treatment of trypanosomiasis it is essential to distinguish the different stages of the disease, as early cases may very possibly be cured by many forms of intravenous medication and may even undergo a natural cure.

Finally, we consider it would be of interest to follow up and note the final results of the treatment of cases at Mbale by Bayer "205" and tryparsamide after at least as long a period as has been possible in the cases treated by intrathecal serum, so that any inference or conclusions drawn thereupon may be comparable.

We would also point out the possibility that such factors as superimposed infection, and also secondary infections (especially of intestinal parasites such as ankylostomes), may interfere with the normal course of any form of treatment.

We wish to thank Dr. J. Hope Reford, R.A.M.C.,

Uganda, for permission to publish this report, and also all those who have helped us in our work, more particularly Captain R. P. Rawson, M.C., late D.M.O., Uganda, and Dr. Mary Martin, Assistant Bacteriologist, Uganda, and Professor John Eyre, of London University, for his criticisms and advice.

REMARKS ON CLAYTON-LANE'S CRITICISM OF MY MONOGRAPH ON MALARIA AND BLACKWATER FEVER IN THE *TROPICAL DISEASES BULLETIN*, 1925, VOL. 22, NO. 4, P. 338.

By H. Ziemann, M.D.

Professor of Tropical Medicine, Berlin.

Criticism may, and indeed should, be severe. It should, however, be just and fair, and based upon facts capable of proof, and not on mere assertions.

(1) The epidemiologic curves of fever in Italy on p. 152 are based, as the text indicates, on the well-known investigations of Celli on the epidemiology of malaria in Italy.

(2) The epidemiological curves in the Cameroons on p. 137 are based on the exact clinical and hæmatological investigation of individual cases. There is no mention of uncertainties.

(3) I have seen cases of recurrence in cases in which gametocytes are present in the peripheral blood, and have explained, not only on p. 307, but also in other places, that other authors (e.g., Nocht) have observed gametocytes also in fresh cases (cf. section on parasites). Wherefore the observations of Warrington Yorke and Macfie, who first found schizonts and then two to three days later found gametocytes in the peripheral blood in new cases, which many sections of my book make objectless, are quite undiscoverable by me.

(4) In many places I have pointed out that the sequels which occur in the inoculated malaria in paralytics cannot without further investigation be applied to the naturally acquired malaria and considered as proved.

(5) Clayton-Lane has not in the least understood my views on the problems of the direct or indirect action of quinine on the parasites (pp. 338 and 356). Compare also Jacues, *Trop. Dis. Bull.*, vol. 14, p. 71.) They are supported by observations on malarial blood after the administration of quinine, and also by the extensive investigations of Retzlaff, p. 364.

(6) He also appears not to have read the sections on quinine injections (intramuscular), wherein I carefully discuss the pros and cons.

(7) Nor does Clayton-Lane completely grasp the chapters on quinine resistance, that a fall in quinine resistance also occurs in cases in which quinine resorption has undoubtedly taken place.

(8) The nomenclature of the parasites is fully explained in the chapter which deals with the parasites.

(9) The circumstance that in one place by a printer's error Delhi is changed to Deli is seized upon by Clayton-Lane as evidence that the credibility of the views in other connections is unreliable. A condition which cannot be obviated by earnest scientists and critics is the seizure, when proof cannot be adduced, of trivialities and inaccuracies. Consciousness and the impartial compilation of works free from transitory errors is recognized, compare, e.g., the criticisms of Grasso in *Il Policlinico* and many others. I cannot, therefore, accept the criticism of Lane as a just and fair one.

ENVIRONMENTAL INFLUENCES WHICH FAVOUR THE DEVELOPMENT AND SPREAD OF THE BILHARZIA PARASITE IN SOUTH AFRICA. FOOD SUPPLY OF "PHYSOPSIS."

By F. G. Cawston, M.D. (Cantab.).

The Presence or Absence of the Intermediate Hosts of Schistosome Parasitic Worms in any Locality Depends upon the Food Supply.

In the Union of South Africa it will depend very largely upon the presence or absence of a common rush of Natal rivers, found also in various parts of the Cape, Transvaal and Free State and existing also in Portuguese East Africa, *Cyperus immensus* C. B. Clarke, for this is the favourite food of *Isidora africana* (Krauss), popularly known as "Physopsis," which is the only common carrier of schistosoma in South Africa.

The plant is found in swampy areas, where, unfortunately, it tends to collect an extraordinary quantity of waste-paper from the homes of Natal Indians, natives and poor whites, who purchase most of their food supply in paper packages, only a proportion of which finds its way into the holes that are dug for rubbish. Incinerators, so well adapted to institutions, are perhaps too expensive to recommend for poorer householders, and the burning of rubbish has its dangers where many children are living in crowded dwellings.

This plant grows abundantly along the banks of a pool at Sydenham, where the vast majority of bilharzia patients in this district have acquired the disease. The pool is about eighty yards long and thirty yards broad. It is particularly the decaying leaves on the surface of the water which harbour examples of *I. africana* and are likely to show the golden jelly containing the eggs. During the dry season accumulated rushes can be burnt, cut down or dug out. The natives gather them and use them for making baskets and mats. *C. immensus* C. B. Clarke might be cultivated for industrial use; but the plant should not be allowed to grow near stagnant water, or where there is the risk of its decaying leaves being carried down-stream. In view of its tendency to encourage the accumulation of rubbish, it should not be grown too close to human dwellings. Fresh-water shells as large as those of *I. africana* are not found in the smaller spruits; nor are they found in marshy areas,

except when they have been carried there in the water that overflows from the flooded river.

I. africana is found less frequently attached to the leaves of the common water hyacinth, *Eichhornia crassipes* (Ponteder) or to floating wood and sugar-cane.

I. africana is also commonly attached to the under-surface of the leaves of the "Blue Lotus," *Nymphæa stellata*, or to some of the stalks, where its eggs may easily be differentiated from those of *Limnæa natalensis* Krauss, the intermediate host of *Fasciola gigantica* Cobbold; because the latter are laid in colourless jelly.

My repeated experiments would seem to show that, whilst examples of *I. africana* seldom fail to become infested, when miracidia of *Schistosomum hæmatobium* are allowed access to the water, *Limnæa natalensis* remains free from bilharzia infection. This observation is in conformity with my experience of *Limnæa* in nature; but it is contrary to that of Dr. Annie Porter, who reports the successful development of *S. hæmatobium* in examples of *Limnæa natalensis* at the South African Institute for Medical Research in Johannesburg.

A careful investigation of the favourite foods of various fresh-water snails is essential to those who attempt to breed them successfully in artificial surroundings.

Where collections of water are known to be infested with the bilharzia and liver-fluke parasites, every effort should be made to clear out the roots of the these common water-lilies and, wherever the lilies are grown, every endeavour should be made to keep them clear of fesh-water snails. In the valley between the two hills at the Bluff, Durban, the "blue lotus" grows extensively, but I do not find any trace of *I. africana* there, nor does this swampy area appear to be conducive to the breeding of this species, and I do not know of any cases of bilharzia infection amongst the numerous Indian children who live in that district.

The dwellings lie close to pools very favourable to the growth of fresh-water snails in the Durban suburbs. A large proportion of these snails harbour schistosomes, and a history of present or past symptoms of bilharzia disease can readily be obtained in most of the neighbouring houses; though it is less frequent amongst the Mohammedans who do not allow their children to hang about the pools. It should be noted that the earlier symptoms of schistosome invasion are sometimes mistaken for malaria in Natal.

The outbuildings, which have been erected so close to the Sydenham pool, are provided with the bucket system. These buckets are said to be emptied three times a week at a cost to the householder of 1s. 6d. a time. I have not examined microscopically the contents of these buckets; but, with so large a number of bilharzia cases in the district, the probability is that they contain the ova of schistosoma, and children with severe hæmaturia sometimes pass their urine among the rushes at the side of the pool. Many Indians have been born in Natal or have migrated to Natal to live amongst the old indentured Indians, and every year sees an increase of their dwellings amongst the natives and the poorer class of European in the Durban suburbs; the vast majority make too little money to enable them to live in much comfort. Although 90 per cent. of the Mohammedan male folk read and speak English fluently, their wives are illiterate, and the vast majority of Indian children are insufficiently intelligent to grasp the significance of a chronic hæmaturia, which so often tends to disappear, more particularly during the winter months.

Durban is very largely dependent on its Indian population for its popular vegetable and fruit supply. This is grown either on Indian property or by Indians in European gardens. It is gathered in the afternoon and stored overnight, being carried in carts driven by Indians to the market in the early hours of the day. At the Indian market a large number of Europeans purchase the daily supply for boarding houses and hotels. Throughout the day Hindu hawkers are to be seen carrying their baskets on bamboo poles round to European houses for the sale of their fruit and vegetables.

Lettuce and kindred vegetables are sometimes gathered and thrown into a pool overnight. I have found such floating vegetables, including the leaves of beetroot, on the surface of the Umbilo River where fresh-water snails breed close to a vegetable garden. Vegetable contamination would seem to have been responsible for bilharzia infection in a child of four who had been protected from other risks of infection.

I have previously drawn attention to the great accumulation of fresh-water snails, particularly *Melanoides tuberculatus* Müller, in the Durban water-cress beds. Although *I. africana* does not breed there, many of the snails are infested with those cercariæ which can encyst on green food. I am glad to note the increased number of well-constructed bore-holes for the supply of water in the Indian quarters; but infested examples of *I. africana* (Krauss) and allied snails are still readily obtainable throughout the Durban suburbs.

Occasionally I find large examples of *I. africana*, less commonly *Limnæa natalensis*, attached to floating cattle manure. The chances of fresh-water snails becoming infested from the miracidia which escape from fæcal material are evident under these conditions; for although the ova of *Fasciola* would appear to take about eighteen days to hatch, the ova of schistosomes hatch out very rapidly in water. The intermediate hosts of trematode parasitic worms are attracted to the surface of a pool by decaying vegetable matter and by the food waste of man and cattle, as is evidenced by the number that are found in such places as a pool below a railway location, a stream below an abattoir, those portions of a river close to the drift where natives or Indians wash their clothes, and marshy land where cattle wade.

In October, 1925, I injected two guinea-pigs with a large number of bifid-tailed cercariæ from *I. africana* collected from the Sydenham pool. No abnormality was detected post mortem in either animal when dissected three months later. How-

er, I fed another guinea-pig on some food con-
ining cercariæ from the same source on October
and 14 and secured about fifty male and female
ult schistosomes from its portal system on
ecember 20, when I also observed a thickened
er-substance and a rather severe ascites. In
ct the animal was dying from ascites when I
crificed it. I have never noted ascites in a bil-
rzia patient in Natal, but this may become
mmon if cases of *Schistosomum mansoni* con-
ue to increase.

I. africana (Krauss) at Durban shows variation
the height of the spire and in the character of
e whorls, as is common in some other species of
is remarkable genus. So great is the variation
some of the species, such as *Isidora tropica*
(rauss) and *Isidora compta* (M. and P.) that one
grets that the term "interspecific hybrids"
ould have been applied to any cercariæ carriers
nong these polymorphous species.

However, *I. africana* (Krauss) may readily be
stinguished from *I. tropica*, *I. natalensis* and
compta, because of the truncate columella of
s shell. This columella may also vary to some
tent and, for this reason, it is sometimes diffi-
lt to tell some examples from those of *Isidora*
Physopsis) *globosa* Morelet, which is a common
rrier of bilharzia infection at Lourenço Marques
nd is said to occur in Natal. The pools from
hich I obtained examples of *I. globosa* infested
ith schistosomes at Lourenço Marques in 1922
ontained numerous examples of the "blue lotus"
nd a thick growth of the broad rush which is so
vourite a food of *I. africana*.

Both *Cyperus immensus* and *Nymphæa stellata*
ccur in the lagoons that are formed at the mouth
f some Natal rivers; but the occasional presence
f sea-water in lagoons prevents an accumulation
f fresh-water snails in any considerable numbers.

In view of the well-known value of sea-water in
estroying the infection of rivers, the local health
uthorities of a Transvaal village were considering
he establishment of a salt-water swimming bath
ontaining 1 in 10,000 of common salt. Such diluted
aline encourages the activity of the bilharzia para-
ites and is favourable to the breeding of their
ntermediate host, and I welcomed the opportunity
f warning them of its danger before the scheme
ad been put in hand and had provided a false
ense of security in an infected locality.

Conclusions.

(1) Pools containing the decaying leaves of the
road rush and the blue lotus are very favourable
o the breeding of the molluscan intermediate
osts of schistosomes, and the mere presence of
ater-fowl cannot be regarded as unfavourable to
he spread of bilharzia infection. So long as these
irds are on the wing, they have access to so large
variety of suitable food supply that only a small
proportion of fresh-water snails are devoured, and
the most mature examples with large shells, which
are the most likely to be infested with cercariæ,
are very likely to escape.

Nevertheless, I have repeatedly observed that similar pools are kept almost clear of fresh-water snails, so long as they contain domesticated duck whose molluscan food supply is limited to what exists in these pools. Generally speaking, the environmental influences which are favourable to wild-fowl are favourable to fresh-water snails, and the control of the intermediate host of *Schistosomum hæmatobium* Bilharz depends rather upon the removal of the decomposing leaves of *Cyperus immensus* C. B. Clarke and those of *Nymphæa stellata* from running water. Fresh-water snails harbouring the cercariæ of *Schistosomum mansoni* Samson often feed on these plants; but they are more commonly found in localities where there is much surface vegetation, such as water-cress, and where they are exposed to fæcal contamination in shallow water.

(2) Those portions of streams which are frequented by man and beast are specially liable to show an accumulation of fresh-water snails, as food waste assists in creating an environment favourable to their breeding and growth.

(3) If *Schistosomum japonicum* could be eradicated from human beings in China and Japan, it might still continue to exist in dogs and oxen; if it were possible to eradicate *Fasciola hepatica* from sheep and oxen in Australia, this parasite would still have the rabbits to use as a reservoir host, as it does to-day in New South Wales. As schistosomes are not known to exist in any animals in South Africa, it is probable that these parasites might be very largely exterminated from the Union, if intelligent efforts were made to cure all human beings who are known to be infested, and the problem of the infection of streams by bilharzia carriers bravely tackled by the public health authorities; for, without the human hosts to assist in the spread of the disease, the country would not harbour influences favourable to its continuance.

The Production of Persistent Alopecia in Rabbits by X-Rays of Various Degrees of Hardness (Harry Clark, Ph.D., and Ernest Strum, *Journal of Experimental Medicine*, October 1, 1925).—The minimum of doses of X-ray, of each of three degrees of hardness, required to produce persistent alopecia of the abdominal skin of normal white rabbits, has been studied. 40 kilovolt rays filtered by 0·5 mm., 50 kilovolt rays filtered by 1 mm., and 70 kilovolt rays filtered by 1·5 mm. of aluminium, were employed. The 70 kilovolt work is unfinished. Under constant conditions of treatment the animals were found to react with a high degree of consistency. The values of the critical minimum doses expressed in terms of ionization (pair of ions per grm. of air divided by 10^{15}) for rays produced at 30, 40, 50 and 70 kilovolt peak, are 2·04, 3·7, 4·5, and over 5·1 respectively. The 30 kilovolt value is taken from a previous paper. It is shown that the alopecia reaction does not run parallel to the erythema and pigmentation reactions.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—**Authors of original communications are entitled to 25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to** THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE **should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

MARCH 15, 1926.

THE DIETETIC THEORY OF PELLAGRA.

PELLAGRA has been defined as an endemic disease, usually of long duration and of unknown causation, which is characterized by cutaneous, gastro-intestinal and nervous symptoms, which undergo exacerbations at recurrent intervals, usually in the spring and autumn.

It was first described by Gaspar Casal in northern Spain as long ago as 1735. His description of the condition, which was known to the vulgar under the name "Mal de la Rosa," was accompanied by a representation of the disease clearly showing the eruption round the neck and down the front of the chest (constituting Casal's necklace) and on the dorsa of the hands and feet. Early in the eighteenth century the disease seems to have been well known in Italy, and it is in that country that the disease has since been best known and most intensively studied. It is, however, very widespread in its distribution, and it is highly probable that before many years have passed, pellagra will be found to be prevalent over the whole surface of the globe. At the present time it is very apt to be overlooked in England and Scotland and in America.

As long as the disease has been known food has always been under suspicion as being a most important factor in its ætiology, and since the area of distribution of the disease in Europe coincided with the districts in which maize constitutes the principal element in the food supply of the people, this substance has often been credited with playing an important part in the production of pellagra. The dietetic theory is still strongly held, and shares with the parasitic or infective theory the views which at present prevail as to the ætiology of the disease. There are very varied opinions as to the precise way in which the disease is produced by maize, and several theories as to its mode of action have at various times held the field. Thus, there is the toxic theory, according to which pellagra is due to the action of toxins produced by or in the maize, it being variously held that the normal grain possesses toxic properties or excites an anaphylactic reaction; that toxins are produced during spring by the germination of the maize; that toxins are generated in the bowel from the grain by the action of *Bacillus coli communis;* and that toxins are produced in fermenting or mouldy maize by the action of many varieties of fungi and bacteria. Another view is the photo-dynamic theory, according to which photo-dynamic substances are elaborated and introduced by maize and other cereals into the blood and become toxic under the influence of sunlight. Again, there is the deficiency theory, according to which the maize protein zein is incomplete in nutrient properties owing to the absence of the amino-acid tryptophane, and in this theory pellagra would be due to a deficiency of tryptophane in a diet composed largely of maize.

Closely allied to this theory is the view of Goldberger that pellagra is solely due to a deficient and unbalanced diet, as he produced the disease experimentally by feeding a group of selected persons on a diet consisting largely of corn-meal, grit, potatoes, fat meat, syrup and sugar—a diet very similar to that of many of the poor, both black and white, in the rural districts of the southern States of North America, where pellagra abundantly prevails

Further, by improvement in the diet of pellagrins the mortality from the disease has been greatly lowered and the time of convalescence considerably shortened.

To Funk we probably owe the view that pellagra is due to a vitamin deficiency and is to be classed as similar to beriberi. McCarrison showed that vitamin C serves to protect the gastro-intestinal tract from infection, and that the deleterious effects of a deficiency of this vitamin is enhanced when the food is improperly balanced, particularly when associated with an excess of carbohydrates or of fats, or of both, in the food. The diet employed by McCarrison in his experiments on monkeys, being deficient in vitamin C and excessive in carbohydrates and fats, is very similar to that employed by Goldberger used in producing experimental pellagra in human beings; but McCarrison insists that faulty food lowers the resistance of the gastro-intestinal tract to infections, whereas Goldberger contends that an unbalanced diet is the sole cause of pellagra. McCarrison, too, was at first inclined to the belief that pellagra is solely a deficiency disease, but later promulgated the view that improper diet is merely a predisposing factor, and that some sort of infection is the exciting cause of the disease.

Seale Harris has pointed out that if faulty food were the only factor in the production of pellagra, it would seem that the countries of Europe, that suffered so much from a lack of meat, milk and eggs during and after the Great War, would have been scourged with pellagra. Notwithstanding the unbalanced and deficient diets during the war in France, Belgium, Germany and Austro-Hungary, pellagra did not prevail in these countries, whilst in Italy there has been so great a reduction in the prevalence of pellagra that it has now become a comparatively rare disease in that country. We must therefore agree with the conclusions to which Harris has arrived, namely, that the cause of pellagra has not been discovered and that an unbalanced diet does not seem to be the only factor in the ætiology of pellagra; that a diet low in vitamin C and unbalanced by an excess of carbohydrates lowers resistance and is an important predisposing cause of pellagra; that a full diet rich in vitamins and a low carbohydrate content is essential in the treatment of pellagra; and that it is due to an infection is probable, especially in individuals whose resistance has been lowered as the result of a deficient or unbalanced diet.

F. E. T.

Annotations.

Non-pathogenicity of the Milkweed Flagellate in Maryland (Francis O. Holmes, *Phytopathology*, May, 1925).—*Herpetomonas elmassiani* (Migone) may be present in the latex of the milkweed, *Asclepias syriaca* L., in very large numbers without appearing to interfere with the normal growth of the plant or to modify the leaves, stems, or seed pods.

The Employment of Carbon Tetrachloride followed immediately by Magnesium Sulphate in the Treatment of Uncinariasis (Clark H. Yeager, M.D., *Transactions of the Royal Society of Tropical Medicine and Hygiene*, October 15, 1925).—The simultaneous administration of magnesium sulphate with carbon tetrachloride has very little effect in reducing the anthelmintic power of the drug, and reduces to a minimum the liability to the production of toxic symptoms. The adoption of this technique in favourable circumstances will effect a great saving of time in mass treatment work, and under certain conditions may make all the difference between the possibility and impracticability of carrying on the hookworm campaign. This technique is more likely to be favoured by the patients on account of the fact that they will not have to wait so long for their first meal as they would have to do with other methods of administering the treatment. In Mauritius this technique has been of no practical use in the treatment of infections by ascaris or trichuris. It is advisable to give or recommend a laxative, when necessary, on the day following treatment, to ensure the early evacuation of dead worms.

Curative Effect of Bismuth Compounds in Experimental Rabbit Syphilis (G. W. Raiziss and M. Severac, *Archives of Dermatology and Syphilology*, November, 1925).—Potassium bismuth tartrate and bismuth compounds in general are much less toxic intramuscularly than intravenously. On the basis of prolonged observations and the method of popliteal node transfer, the authors found that bismuth compounds are powerful enough to cause complete eradication of infection in experimental rabbit syphilis. Arsphenamin and its derivatives have higher chemotherapeutic indexes than bismuth compounds. The latter are distinctly superior to mercury. Because the low toxicity of arsphenamin derivatives permits the intravenous administration of massive doses, they remain the basic remedies in the treatment of syphilis, bismuth compounds taking the next place.

Mycosis Fungoides. Its Relation to Leukemia and Lymphosarcoma (J. Frank Fraser, M.D., *Archives of Dermatology and Syphilology*, December, 1925).—Two cases are added to the growing number of instances of mycosis fungoides in which the pathologic changes in the tissues are unquestionably neoplastic. Evidence is presented which shows a genetic relation between mycosis fungoides, lymphatic leukæmia and lymphosarcoma. The name reticulum cell sarcoma is suggested to replace the term lymphosarcoma in describing the lesion of mycosis fungoides. The suggestion is based on the assumption that the lesion has its origin in the reticulum cells of the papillary layer (reticulo-endothelial system of the skin).

The Effect of Ancylostome, Ascaris, and Trichuris Infections on the Health of the West African Native (R. M. Gordon, *Annals of Tropical Medicine and Parasitology*, December 16, 1925).—A study of the effects of ankylostomiasis on the health of the West African natives, and those of *Ascaris* and *Trichuris* on eighty-nine of the same cases has shown that these infections or a combination of these infections, produce no noticeable effects on the hæmoglobin percentage, the physique and general fitness, or the mentality of the cases examined, nor is their presence in any way associated with albumin or casts in the urine. *Ascaris* and *Trichuris* infections do not appear to be more associated with a low standard of energy than one of a higher standard. On the other hand, the figures suggest the possibility of some association between ankylostome infections of more than 15,000 ova per grm. of fæces, and the low standard of energy observed in such cases; but only a few such intense infections were observed, and it is obvious that in order to justify any such definite conclusion the work must be repeated with very much larger groups of cases. It therefore follows from these conclusions that before treatment, and especially before the so-called " mass treatment " of ankylostomiasis, is applied to any native race, careful investigation should be made whether ankylostomiasis has any definite pathogenic effect on that race, and if pathogenic effects are noted, with what degree of infection they are associated.

Erythrocytosis in Artificially-inoculated Malaria (G. de M. Rudolf and J. C. Ramsay, *Annals of Tropical Medicine and Parasitology*, December 16, 1925).—In four cases of general paralysis inoculated with benign tertian malaria an erythrocytosis was found to precede the anæmia. The erythrocytosis occurred whether the inoculation was performed by means of mosquitoes or by subcutaneous injection of malarial blood. It was independent of the sex of the patient and of a history of previous malaria. The succeeding anæmia occurred, or persisted for several days after the cessation of the fever. Regeneration of the red cells was complete within three weeks, although the degree of anæmia was very different in the four cases. An erythrocytosis was found to follow the anæmia. The hæmoglobin was found, in two cases, to vary with the red cells, but regeneration was less rapid. The colour-index was, as a rule, of the secondary anæmia type. At certain periods it became as low as 0·5. In two cases the number of parasites was found to vary approximately with the degree of fever, although the number of parasites was very different in the two cases.

Anti-rabic Procedure in Palestine with Special Reference to Decentralization of Treatment (G. Stuart, M.A., M.B., and K. S. Krikorian, M.D., *Annals of Tropical Medicine and Parasitology*, December 16, 1925).—Carbolized anti-rabic vaccine is an efficient and safe treatment for persons bitten by rabid animals. It can be manufactured without additional staff in any well-equipped laboratory. It can be distributed to any number of treatment centres where as good results attend its use as at the place of its production. Better results have followed the employment of a dosage of 5 c.c. daily of 1 per cent. emulsion, over a period of fourteen days, than of 2 per cent. of the same emulsion over the same period. Carbolized vaccine is most practicable in the curative and prophylactic treatment of farm animals. It can be easily administered in rural districts by veterinary officers. It is a great advance on older methods of treatment in the wideness of applicability and economy of production of the vaccine. It is at once the most economical and utilitarian mode of treatment. Bitten persons can be treated at or near their own homes, and thus—the all-important consideration of immediate treatment aside—they are spared the expenses connected with travel to, and residence in, a strange town.

Stool Examination for Protozoa (Walter S. Thomas, M.D., and E. A. Baumgartner, M.D., *Journal of the American Medical Association*, November 28, 1925).—In 1,122 inmates of a New York State institution, 44·47 per cent. showed intestinal protozoa on examination of a single stool specimen from each. There is evidence of cross infestation in the institution. The influence of age is not great except in the case of *Giardia lamblia*, in which the young persons are more often infested. *Chilomastix mesnili* was the organism most often found. *Endamœba histolytica* was seen in only 1·97 per cent. of those persons examined. Taking this low figure into consideration, together with the facts that we are dealing with a class of patients in which a high incidence might be expected, that the patients were all confined in an institution where cross infestation takes place, and that none of the 1·97 per cent. with *Endamœba histolytica* had at any time shown evidence of amœbic disease, we feel justified in believing that *Endamœba histolytica* plays only an insignificant rôle in the production of disease in New York State.

A Study of Hemolytic Streptococci in Acute Rheumatic Fever with an Analysis of the Antigenic Relationships existing among certain Strains (Christopher H. Andrews, M.D., Clifford L. Derick, M.D., and Homer F. Swift, M.D., *Journal of Experimental Medicine*, January 1, 1925).—Thirteen strains of hæmolytic streptococci isolated from patients with acute rheumatic fever did not show any evidence of being related serologically. Strains of hæmolytic streptococci exist which, although identical by the agglutination test, do not show complete reciprocal agglutinin absorption. Sera

prepared from such related strains may show some protective power in mice against another member of the group. Some strains of hæmolytic streptococci may absorb agglutinins from a serum prepared against another strain, and yet may fail to be agglutinated by that serum. None of twenty strains of hæmolytic streptococci isolated in New York City in 1924 and 1925 corresponded serologically with Dochez, Avery and Lancefield's 4-type strains or with Gordon's Type I strain.

The Incidence of Pulmonary Tuberculosis in Colombo as Indicated by an Examination of Sputa found in Public Places (R. de Silva, *Ceylon Journal of Science*, Vol. 1, Part 3, November 18, 1925).—In the streets and public places of Ceylon two types of sputa are to be seen scattered widely, one a reddish brown liquid which is ejected by the numerous chewers of "betel"; the second type is gelatinous, derived principally from bronchiole secretions brought up from the lungs. 148 specimens of the latter type were collected for examination for *Bacillus tuberculosis*. 3·8 per cent. were found positive for this organism. Many of the specimens contained numerous streptococci and diphtheroids, and in one case a specimen was seen to be teeming with spirochætes indistinguishable from the spirochætes of Vincent's angina.

The Treatment of Hookworm and Ascaris Infections with Carbon Tetrachloride and Oil of Chenopodium (W. C. Sweet, *Ceylon Journal of Science*, Vol. 1, Part 3, November 18, 1925).—The most efficient treatment tested for removing hookworms was a combination of carbon tetrachloride and oil of chenopodium, in a ratio of three to one, given in a solution of magnesium sulphate for a purge. This combination was also highly efficient in removing ascarides, although the giving of the salts two hours after the anthelmintic increased the efficiency in removing these worms. In a country where infection with *Ascaris lumbricoides* is widespread, the combination treatment given in the purge of magnesium sulphate will be a better routine measure than either of the anthelmintics given alone. In the series of treatments reported no decided preferential action on hookworms of either sex could be determined.

The giving of salts with the anthelmintic apparently delayed the expulsion of the majority of both hookworms and ascarides until the second day following treatment, but increased the efficiency of the trial treatment in removing hookworms. The degree of infection with hookworms was found to have some effect on the efficiency of trial treatments, the highest efficiency being found in groups with from 51 to 200 worms each. Infections with smaller and larger numbers of worms did not show as high an efficiency for trial treatments.

Hookworm Re-infection. An Analysis of 8,239 Ceylon Egg-counts (W. C. Sweet, *Ceylon Journal of Science*, Vol. 1, Part 3, November 18, 1925).—From an analysis of 8,239 Stoll egg-counts made in Ceylon, previously treated persons were found to have a considerably lower infection intensity than untreated persons, the reduction being greatest in the children's groups. Re-infection with hookworms subsequent to treatment was found to be most rapid in the first three years after treatment. Between the third and seventh years after treatment intensity rates remained at a level, with variations of less than 12 worms, and then began to rise. The percentages of persons found infected showed an initial sharp rise and then a small steady increase. The average length of life of the adult hookworm was suggested to be between three and five years. The importance of sanitation was upheld, but it was argued that the impossibility of immediately introducing adequate sanitation was no bar to the eventual accomplishment of hookworm control.

Intensity of Hookworm Infestation in Alabama. Its Relation to Residence, Occupation, Age, Sex and Race (W. G. Smillie and D. L. Augustine, *Journal of the American Medical Association*, Dec. 19, 1925).—True hookworm disease as a real economic menace to the welfare of the people in Alabama is limited to the rural white children of school age. Hookworm infestation is widely distributed among all ages, social, economic and racial groups. The persons with light infestations are not to be ignored, for they are hookworm carriers and are potential sources of danger to the community. They are not cases of hookworm disease, however, and should be considered as such. If these facts are true for Alabama, they are probably also true for the other coastal plain, Southern States having a similar type and distribution of population, and similar climatological and geological conditions. Sanitation and education must be the chief modes of control of the carrier. Long experience by many workers has clearly shown that treatment alone is of little avail in the control of incidence of infestation in an area favourable to development of hookworm larvæ.

Factors that Influence the Rate of Increase of Hookworm Infection (W. A. Sawyer, *The American Journal of Hygiene*, November, 1925).—The conclusions of this study are as follows: For every infected community, at a given time, there is a level of equilibrium of intensity of hookworm infection, which may be defined as the average number of worms per person which would be present if the existing conditions had been constant over a long preceding period of years. If the environmental conditions affecting hookworms are fairly constant and unaffected by control operations, this level of equilibrium would be approximately equal to the aver-

age number of hookworms per person, as ascertained by an adequate series of egg-counts or worm-counts.

When the intensity of infection is at equilibrium, two factors, or sets of forces, are balancing each other. One is the effect of density of hookworm "population" on the rate of reproduction, as the terms are used in this discussion; in general, the rate of reproduction rises with a decrease in the density of population. The other factor is the effect of the complex combination of environmental conditions which affect hookworms and their ova and larvæ.

Mortality curves for the two species of hookworms infesting man would be very useful. A method is suggested for ascertaining them. Until the essential data have been collected, the principles advanced in this article and the assumed curves, based on those of *Drosophila*, may be used in planning hookworm control operations, but the curves will require much correction with growing experience and should be replaced as soon as possible by data based on observations on hookworms.

Bismuth in the Treatment of Syphilis (Surgeon Commander R. J. G. Parnell, *Journal of State Medicine*, January, 1926).—After two years' experience of metallic bismuth in the treatment of syphilis the author has come to the following conclusions, but he does not offer them as the last word upon the subject.

Bismuth must not be considered a substitute for the salvarsan-type drugs. It is inferior to Ehrlich's preparations, but superior in every respect to mercury. Compared with mercury it is less toxic, exercises a more powerful influence on manifest lesions, and appears to affect the serum Wassermann to a greater extent. It is very valuable in cases intolerant of, and unsuitable for, arsenic therapy. In certain cases where prodromal treatment is desirable, before establishing arsenical therapy, bismuth is safe and efficacious. In the school which favours adjuvant treatment, bismuth should replace, and to a large extent has replaced, the use of mercury.

Bismuth would appear to have especially beneficial effects upon cases of glossitis and chronic leukoplakia of the mouth. It is tolerated well by cerebro-spinal cases, and evidence is accumulating that it apparently influences favourably the meningeal involvement. It can be given safely to cases of arsenical jaundice. In old cases of syphilis (latent cases) it appears to be the equal of salvarsan and neo-salvarsan in its influence upon the Wassermann reaction, but there is not sufficient evidence to justify any statements to the effect that the negative reactions obtained are permanent ones.

Contribution to the Question of Dysentery Carriers in the Philippine Islands (Ana Vazquez-Colet, *The Philippine Journal of Science*, October, 1925).—The author has demonstrated the existence of healthy carriers of *Bacillus dysenteriæ* in the Philippine Islands by the isolation of cultures which, according to standard methods of identification, proved to be *B. dysenteriæ*. In 3,328 examinations 14 carriers were found, of whom seven harboured the Shiga type, six the Flexner type, and one both Flexner and Shiga types successively. Agglutination tests were performed with the carriers' sera and with the corresponding cultures isolated from the carriers, as well as with stock cultures of the Shiga and Flexner types. Usually the serum of the carrier agglutinated its own strain to a lesser degree than the stock cultures, and at times a considerable inhibition zone was noticed with the carriers' serum and its own strain. All of the cultures belonging to the Shiga type, isolated from the carriers, were pathogenic for white mice, and some of them were strongly toxic to rabbits. The cultures belonging to the Flexner type, isolated from the carriers, were found to be of low virulence.

Ætiology of Granuloma Inguinale with a Clinical Report of Three Cases (L. H. Cornwall and S. M. Peck, *Archives of Dermatology and Syphilis*, Nov. 1925).—In all the three cases studied organisms believed to be identical were isolated. Lesions resembling clinically and pathologically those observed in human cases were reproduced in rabbits by intracutaneous inoculation, and an organism believed to be identical with the one cultured from human lesions was obtained in cultures from rabbit lesions. Lesions were produced by reinoculation from rabbit to rabbit, and an organism was recovered from the second rabbit apparently identical with that isolated from human cases. The organism isolated has a characteristic morphology in young cultures on Sabouraud's medium. This morphology disappears in old cultures and is not reproduced in subcultures. It is the authors' belief that the organism described is the causative factor of granuloma inguinale.

Miliary Lichen Planus. Report of Case (E. R. Maloney, *Archives of Dermatology and Syphilology*, November, 1925).—It would appear from the study of the case described that there are cases of lichen planus of a rather unusual type for which, because of the character of the papules, the name miliary lichen planus as applied by Pels would be appropriate. Crocker uses the term "acute miliary lichen planus" in describing a very different type of the disease—a severe acute form which may be primary or which may occur on an existing eruption, and which is attended with serious constitutional symptoms and in rare cases even terminates in death. The papules in these cases, however, seem to be typical lichen planus papules, and although small, are generally arranged in a more or less typical way. They are bright red, and itching is a prominent and often severe symptom.

A Field Study of Mountain Malaria in Brazil (Nelson C. Davies, *American Journal of Hygiene*, January, 1926).—An examination was made of 201 persons living in railroad construction camps in the mountains near Andra dos Reis, State of Rio de Janeiro, Brazil. Thirty-nine infected individuals were found, of whom ten were gametocyte carriers. The predominant local anopheline mosquito was *A. bellator*, known in Brazil as *Anopheles* (or *Myzomyia*) *lutzi*. In a series of over 400 stomach dissections of this species one cyst was found, in a mosquito captured while biting a *vivax* gametocyte carrier. More than 150 of the mosquitoes examined were known to have fed on the blood of gametocyte carriers. This mosquito, therefore, shows an extremely low grade of susceptibility to infection with plasmodia. The presence in the locality of the following additional anopheline mosquitoes was verified: *A. eiseni* (*A. tibiamaculatus*), *A.* (*Myzorhynchella*) *lutzi*, and *A.* (*Cellia*) *argyrotarsis*. It is suggested that the last-named species is probably responsible for a large part of whatever new infections occur in the region. Much fever is attributable to relapses.

Epidemic Disease in West Africa. The Menace of the Future (N. A. Dyce Sharp *Trans. Royal Society of Tropical Medicine and Hygiene*, October 15, 1925).—It would appear that louse-borne relapsing fever was introduced into West Africa in 1920 with the return of the Senegalese troops from the European war area. Drs. Kerrest, Gambier and Bouron reported that relapsing fever first occurred in epidemic form in 1921, in the French Sudan, at Mati on the Niger where the troops were assembled prior to disbandment. The mortality at that time was between 12 and 17 per cent. It was by this route that the disease entered West Africa, where it is a scourge to the native. The initial outbreak of relapsing fever in B.W.A. was on the Gold Coast in July, 1922, among the Zabermawa colony in Accra. These people are sometimes known as Malakala, a term applied to travelling beggars, and are noted for their untidy appearance, uncleanly habits, and notorious lousiness. They come to Nigeria to do odd jobs during the dry season, returning to their country for the rains. The Zabermawa kola traders were responsible, it is believed, for the introduction of plague into Nigeria from the Gold Coast in July, 1924. As introducers of two new deadly diseases into B.W.A. these people are a great danger to the country, and it is feared that before long other diseases, such as typhus, cholera, &c., will make their appearance unless adequate precautions against invasion are taken in time. The types of relapsing fever prominent in Nigeria resemble the Indian forms. The organism is not unlike *Spirochæta carteri*. The disease in West Africa resembles malaria and influenza in its protean character, and readily yields to appropriate treatment.

A Report of Typical and Atypical Bacillus dysenteriæ Shiga, with Special Reference to Agglutination Reactions (G. R. Lacy, *The Philippine Journal of Science*, November, 1925).—Forty-five strains of bacilli similar to and identical with *Bacillus dysenteriæ* Shiga have been studied in this series. Serologically, twenty-seven strains formed one group which corresponded to typical *B. dysenteriæ* Shiga, and nine others formed a heterologous group agglutinated only by their homologous immune sera. The members of the large agglutinable group and the inagglutinable group were indol-positive with two exceptions. The two smaller groups corresponded culturally to the Schmidtz bacillus, while the larger group corresponded to the Shiga-Kruse group of true *Bacillus dysenteriæ*. The members of the three different groups were pathogenic for rabbits. Polyvalent antidysenteric serum afforded protection against experimental inoculation with cultures of all three groups.

Abstract.

VIBRIOS IN HUMAN EXCREMENT.[1]

By K. Vallipuram,
and
W. R. de Silva.

Non-pathogenic vibrios are very rarely seen in smears of stool, and they are seldom isolated during the usual cultural examinations for the presence of *Vibrio choleræ* in suspected material.

During an outbreak of cholera in the North Central and Eastern Provinces of Ceylon rectal swabs of specimens of stools were examined from 1,180 contacts for the detection of temporary carriers of cholera. Vibrios were isolated from 11 of these persons, and nine of these organisms by cultural and agglutination tests were proved to be *V. choleræ*. The other two vibrios did not agglutinate with anticholera serum even in very low dilutions. They were morphologically indistinguishable from cholera vibrios and each organism had a single terminal flagellum.

Vibrio No. 1 gave the same cultural reactions as *V. choleræ;* but it reduced nitrates to nitrites to a smaller degree than *V. choleræ*. It produced acid in lactose, saccharose, mannite, maltose and glucose, and liquefied blood-serum and slightly clotted milk which later became peptonized.

Vibrio No. 2 did not produce acid in glucose nor reduce nitrates nor form indole in peptone water nor liquefy serum.

The man who harboured Vibrio No. 1 had not suffered from gastro-intestinal derangement. The organism was isolated on four repeated occasions and was present in the man's stool three weeks after the first occasion on which it was isolated. This

[1] Abstracted from the *Ceylon Journal of Science*, vol. i, part 3, November 18, 1925.

contrasts for persistence with *V. choleræ*, which disappeared within ten days from the stools of all the nine contacts who had harboured it.

Serum which agglutinated this organism was easily prepared; after two injections of a peptone water culture into a rabbit, the rabbit's serum agglutinated the organism in a dilution of 1 in 1,000, but did not agglutinate *V. choleræ*. Vibrio No. 2 was partially agglutinated in dilutions up to 1 in 200 by this anti-serum; but it differs so markedly in cultures that it is obviously a different organism.

Vibrio No. 1 differs from the Finkler Prior Vibrio by producing indole and from *V. metchnikovi* by the fact that it is not pathogenic to guinea-pigs and fowls.

Serum which agglutinated Vibrio No. 2 was also prepared, and it agglutinated the organism in dilutions of 1 in 1,000, but did not agglutinate *V. choleræ* nor Vibrio No. 1.

We can find no description of vibrios which agree on all cultural tests with the vibrios. Bergey, in his latest manual, describes 11 species, but not one of these is similar to either of the vibrios here described.

Dr. Castellani has described an organism which he named *Spirillum zeylanicum* in 1910, *Vibrio zeylanicus* in 1913, *Bacillus zeylanicus* in 1913, *Vibriothrix zeylanica* in 1917, and *Streptobacillus zeylanicus* in 1918.

We have isolated this organism on one occasion from fæcal matter. It is an exceedingly polymorphic bacillus, and although occasionally curved forms are seen, it is obviously not a vibrio, and could not be mistaken for *V. choleræ* or any other well-marked vibrio.

Current Literature.

Bulletin de la Société de Pathologie Exotique. October 14, 1925.

Investigations on Plague in Cambodia in 1924, carried out at the Laboratory of Pnom-Penh (E. Le Cousse).—The results of these investigations show that plague exists to a large extent at Pnom-Penh. Of 1,065 organs examined 103 showed positive diagnosis of the disease besides other doubtful cases. Nine cases were infants up to 2 years of age; 7 cases were found in children from 2 to 5 years, and 88 were over 5 years, the greater number in adolescents and adults; very rarely was the disease found in old people. In 1924 the majority of cases were of the bubonic form. There was no case of pulmonary or of dysenteriform plague. Investigations for intestinal amœbiasis gave 224 positive cases.

Two New Cases of Cutaneous Leishmaniasis observed in Natives of Morocco in the Region of Fez (P. T. Flye Sainte-Marie and A. Mansouri).—The first case of cutaneous leishmaniasis was reported in this bulletin in 1924 by Dekester and Melnotte. Two further cases have been obser in men aged respectively 35 and 45 years. T disease is apparently very rare in North Moroc as only sporadic cases are seen, but prolon investigations would no doubt bring to light imp ant centres where it is endemic or establish presence of other sporadic cases.

American Leishmaniasis of the Frontal Sin Favourable Treatment by Iodide of Quinine a Bismuth (E. Escomel).—The author has obser a very curious case of American leishmaniasis in woman of 40 years of age. She had lived at As lero, south of Peru, for fifteen years. Fifteen da after her arrival, when going to bathe in the riv she was bitten by an organism which she did n see. She scratched, but gave no importance to t bite. It was later transformed into a papule, a then into an ulcer which she could not cure, no withstanding the many treatments she tried. year after she left for Arequipa, and after anoth year the ulcer was apparently cured. Six mont ago the infection broke out again after having be latent for thirteen years, although she had be living in a cool town. The region of the nose an forehead was most painful. The nasal extremit was hypertrophied and ulcerated, and abundan leishmania were found in the thick yellow liqui from the crusts. The interior of the nose was als badly ulcerated. The region of the frontal sinu was swollen and painful. American leishmaniasi clinically resembles syphilis. Iodobismuthate o quinine in conjunction with intravenous injection of emetin caused rapid amelioration.

Epidemiological Study of a Plague Centre in South-East Russia (O. Aristarkhova).—In June, 1924, being notified of the death of three Kal moukes, the author went to investigate at the place indicated. As is the custom in these parts, the inhabitants had fled to the Steppes after having buried their dead. Autopsy of the deceased subjects proved that they had died of broncho-pneumonial plague. On questioning the Kalmoukes, who were found 12 km. away, it was found that the father, aged 35 years, and his younger brother had died of the disease between four to five days; the wife also got ill and died at the end of two days. Among the 35 people who had fled, two women and a girl of 4 years were ill; the women died between one and two days and the girl recovered. During the following days several others got ill and died. Yersin bacilli were found in all the sputums and characteristic lesions of broncho-pneumonial plague were found at autopsy. The savage rodents of the place were examined; the spermophiles were found to be carriers of plague bacillus. Some days afterwards another case was reported, which proved to be bubonic plague. Contamination had apparently been brought about by lice on cats, who had eaten savage rodents but had remained in demnified.

Note on a Herpetic Virus of Moroccan Origin (T. Remlinger).—The patient was a native of

Morocco, 18 years of age, and worked in the laboratory of the Pasteur Institute. On July 11 he suddenly developed a severe attack of fever. He was sent home, but came to the Institute the next day saying he felt quite well, and he resumed his work. The following day he was greatly distressed, his lips being very much swollen and almost entirely covered with large blisters. The eruption spread inside the mouth and later ulcerated badly, rendering the partaking of food impossible. There was no fever. In three days the patient was cured. A quarter of a cubic centimetre of the liquid from the blisters was inoculated into the brain of a rabbit on July 13. Nothing happened until the fourth day after inoculation, when the animal appeared ill, had abundant saliva, roamed round the cage, and looked as though he were trying to play the drum. On the sixth day he hardly moved. A thick, abundant, muco-fribinous exudate came from the anus; there was a violent epileptic crisis, and the animal died. Autopsy was completely negative. Four other rabbits inoculated by trepanation with the same substance died of typical herpetic encephalitis between four to six days after inoculation. The virus acquires a fixed pathogenicity when inoculated successively into rabbits and regularly causes death the third day. The experiments prove that the virus from Morocco in no way differs from that in Europe.

Tokelau (Tinea imbricata) in the Chinese Province of Honan (G. Villain).—Tokelau has been known to exist in the southern or tropical part of China for some years, but this is the first case described in the northern regions. The patient was 37 years of age, a native of Shantung, but had lived at Honan for a long time. He was a carpenter by trade. Nothing notable in his past history or in that of his antecedents. He had been infected for about three years, but could not give any precise details as to the beginning of the disease or its evolution. When seen by the author the patient presented a dermatosis on the gluteal region, the thighs, and inguinal region. On the arms there were a few concentric lesions, though nothing was visible on the other parts of the body. A fungus isolated from this case showed all the characteristics of *Tinea imbricata* described by Castellani, and differed notably from the *Tinea sabouraudi* of Sabouraud.

Three Cases of Enteritis due to Trichomonas cured by Stovarsol (Mme. A. Panayotatou).—During the years 1915-21, 709 specimens of stool have been examined at the Greek Hospital at Alexandria. 428 were positive for amœbæ, 93 were positive for *Trichomonas*. The percentage of infected cases was greatest in 1920, i.e., 23·8. Although the number of cases of dysentery and enteritis due to *Trichomonas* is not very high, the parasite must be considered as the cause of serious intestinal troubles. This has also been noted by Brumpt and Marchoux. The author describes three cases of intestinal infection in which no other agents but trichomonas were found, and which yielded to stovarsol after all other medicaments had failed. Besides being very effective in treatment, stovarsol is administered without any difficulty by the mouth, and is less expensive than treatment by injection.

Filariasis in a European in New Caledonia (R. Herrmann and J. Genevray).—Animal filaria are very numerous in New Caledonia; human filaria have been observed by several authorities, but the disease is not very frequent, especially among Europeans. No case has been reported since 1911. The present case was the first detected during the authors' three years investigations, and was caused by *Filaria bancrofti*. The patient, aged 13 years, had never left the colony; she was anæmic and presented pronounced hemato-chyluria. The first examination of the urine, October 30, 1923, showed 5 to 9 filaria embryos per field. November 6 about 6 microfilaria were found in each drop of blood examined. Injections of sulfarsenol cured the patient, and all further examinations for filaria were negative until December, 1924, when one microfilaria was found in the blood, but the patient considered herself cured and refused treatment and further examinations.

Intestinal Bilharziasis in the Form of Abdominal Tuberculosis (H. Fabre).—Guadeloupe is an important centre of intestinal bilharziasis, which had hitherto been ignored. It was only by microscopical examinations that the disease was detected; in one year about fifty cases have been observed, three of which presented interesting symptomatological characteristics. The three cases, aged 5, 13 and 22 years respectively, were suffering from evening fever and chronic constipation, no other visible symptoms, and were thought to be suffering from intestinal or pulmonary tuberculosis. Examination of the stools showed the presence of numerous eggs of *Schistosomum mansoni*. Treatment by intravenous injections of emetin was effective.

Anopheles in the Higher Regions of Corsica. Presence of A. bifurcatus and of A. plumbeus in the North and South of the Island (A. Catanei).—During the summer of 1925 the author made investigations in the high northern regions of Corsica and along the East and West Coast. Numerous sites of anopheline larvæ were found almost everywhere. The parasite lives in the larval state in all stagnant and slow flowing waters. Except at Corte, where malaria has been known to exist for some time, the other regions were believed to be exempt from the disease.

THE INDIAN MEDICAL GAZETTE.
January, 1926.

Cholera in the Punjab. An Epidemiological Note (C. A. Gill).—Punjab contains no permanent foci of cholera, and in almost every instance outbreaks of the disease in this province are directly or indirectly traceable to importation of infection

from outside the province. In the majority of cases the disease appears to be introduced by Hindu pilgrims from Bengal, Bihar and Orissa, the endemic home of cholera. There was a mild epidemic in the summer of 1924 in Punjab, with the result that 4,118 cases and 3,551 deaths occurred, as compared with 25 cases and 11 deaths the previous year. The course of the malady was normal and completely disappeared in November, and from this time up to the beginning of April, 1925, the province was free from cholera. In April there was a small outbreak amongst Mohammedans. Subsequent investigation showed that infection was conveyed to an adjacent village in the Salt Range, where a large fair, attended by some 50,000 people, was being held. On April 12 there was an explosive outbreak of cholera involving several hundred pilgrims who were dispersing to their homes. The early cases of cholera are rarely typical, and there is a strong tendency to hide the existence of the disease until the completion of the religious ceremonies that usually culminate in a ceremonial ablution and drinking of the sacred waters on the last day of the fair. The manner in which the first town became infected could not be determined. In about ten days 800 cases and 320 deaths occurred solely among the pilgrims in eleven different parts of the province. The total number of cases and deaths from cholera from April 1 to August 8, 1925 was 5,841 and 2,129 respectively. This is the worst outbreak that has occurred during the past thirty years. The most interesting epidemiological features in this outbreak are, firstly, the appearance of cholera in epidemic form in April instead of the normal season, July-September. Secondly, the spread of infection from the north instead of from the endemic area in the United Provinces. Thirdly, the epidemic involved Mohammedans in its early stage instead of Hindus, which is generally the case.

On a Species of Trichomonas Prevalent in Calcutta (B. Mohan das Gupta).—The results of these investigations are that the prevalent type of human intestinal trichomonad in Calcutta is *Pentatrichomonas ardin delteilli* (Derrieu and Raynaud), 1914. *Pentatrichomonas* is a parasite with a tropical distribution, whereas *Trichomonas, sensu stricto*, is a parasite rather of temperate zones. As to its pathogenicity or non-pathogenicity to man nothing definite can yet be said. It can be readily cultivated in Row's hæmoglobin-saline medium at 37° C.; at 22° C. and lower temperatures cultures die within twenty-four hours. A strain has been kept alive in Row's medium by sub-passage every third day, for sixty-three days. When kittens are fed with rich cultures of this parasite, viable flagellates pass unchanged through the stomach and intestine and settle in the cæcum, where they appear to be able to establish a localized infection. The test for the viability of these forms was by culture. This appears to confirm Kofoid's suggestion that *Pentatrichomonas* infection in man may be acquired, not by swallowing cysts, since the cumulative work of many investigators has failed to discover such cysts, but by ingestion of the flagellate in its motile and vegetative form.

An Account of an Outbreak of Cholera at Goalundo Ghat (W. J. Marshall).—During the period September 19 and October 8, 1925, 24 cases of cholera were admitted to Goalunda Ghat Hospital, all of whom recovered under treatment with atropine, hypertonic saline and alkalies.

The Occurrence of Urticaria in the Treatment of Malaria by Quinine (T. A. Hughes).—Two cases of malaria are described; in one quinine produced a marked urticarial eruption all over the body, while in the other it aggravated a generalized urticaria already existing as a result of the malarial attack. In the first case the rash was not alleviated or prevented by bromides or calcium lactate, but hypodermic injections of adrenalin hydrochloride about five minutes after each dose of quinine had a very good effect on the urticaria. In the second case, adrenalin administered as in the first case did not benefit the skin condition, but prevented its aggravation by quinine. On the other hand, calcium lactate in 30 gr. doses seemed to bring relief, but bromides were without effect. The eruption disappeared on the fourth day after admission and the patient left hospital.

A Case of Kala-azar in the Simla Hills (B. J. Bouche).—The case described is one which is often mistaken for chronic malaria. The patient, an Anglo-Indian girl, arrived at Jutogh, Simla Hills, from Sanawar with a statement from a medical officer that she was suffering from anæmia, the result of chronic malaria. She was ill-nourished and emaciated, enlarged spleen, temperature 99·4° F., liver slightly enlarged downwards. Blood negative for malaria. Had fever eight years ago which was suspected to be kala-azar. Has had fever of low, irregular type, and was repeatedly treated for malaria with no benefit. Frequently in hospital and had been in association with a case of kala-azar there, she was also in contact with her aunt, who was suffering from the disease. Injections of quinine bihydrochloride. Urine showed marked chyluria, and a large number of microfilariæ were present. The quinine was increased to 10 gr. t.d.s. and a mixture of tinct. ferri perchlor. and glycerine was added as an antifilarial measure. The patient's appetite was retained throughout the fever. The finger blood was examined for the fifth time for malaria without success. Leishman-Donovan bodies were seen in three large mononuclear leucocytes. On the fifth day of treatment the chyluria had disappeared, but the filariæ still persisted in the urine. A few days later a severe urticarial eruption broke out immediately after the urea stibamine injection, accompanied with nausea and vomiting, but it only lasted for half an hour. After three months' treatment the patient was completely cured.

Original Communications.

ANKYLOSTOMIASIS: COMPARATIVE EFFICIENCY OF CARBON TETRACHLORIDE, CHENOPODIUM AND THYMOL IN THE TREATMENT OF HOOKWORM INFECTION.

By C. MANALANG.
Philippine Health Service.

THIS report deals with the results obtained from three drugs (carbon tetrachloride, chenopodium and thymol) used against hookworm as observed in cases treated in Zamboanga General Hospital. About 95 per cent. of the cases were Filipinos.

Carbon tetrachloride was given as follows: The patient takes no supper or breakfast; at 6 a.m. he is given 1 c.c. of carbon tetrachloride for every 5·5 kg. of body weight. The drug is given in a little water and all alcoholic medicines suspended during the treatment. He usually develops dizziness and occasionally vomits. Should vomiting take place before half an hour has elapsed after taking the drug, another dose is given. The patient should lie down to avoid vomiting. The bowels often begin to move half an hour after taking the drug, and three to seven additional stools follow within 24 hours. The drug was also given in doses of 1 c.c. for every 7 kg. and 10 kg. of body weight, and in combination with saturated solution of magnesium sulphate, 4 c.c. of carbon tetrachloride was the maximum dose for adults, and in the following combinations according to age:

(*a*) 10 drops of carbon tetrachloride and 15 c.c. magnesium sulphate	1 to 5 years
(*b*) 1 c.c. of carbon tetrachloride and 20 c.c. magnesium sulphate	5 to 10 ,,
(*c*) 2 c.c. carbon tetrachloride and 25 c.c. magnesium sulphate	10 to 15 ,,
(*d*) 4 c.c. carbon tetrachloride and 45 c.c. magnesium sulphate	adult

Chenopodium was given as follows: The night before treatment, supper consisted of soft boiled rice. (During the day of the treatment only milk was given.) At 6 a.m. 1·5 c.c. of chenopodium (freshly filled into gelatine capsules) was administered; at 8 a.m. the same dose was given, and at 10 a.m. 40 c.c. of saturated solution of magnesium sulphate was administered. The dose for children was computed according to the standard rule.

Thymol was administered as follows: No food of any kind was taken in the morning of the treatment. At 6 a.m. 1·3 grm. in one capsule and at 8 a.m. another capsule of 1·3 grm. was administered. At 10 a.m. 45 c.c. of saturated solution of magnesium sulphate. This applies to the dose for adults.

After all the above described treatments, all the bowel movements were collected for 24 hours in the case of carbon tetrachloride, and 48 hours in the cases treated either with chenopodium or with thymol. Practically no hookworms were recovered in the second 24 hours' stools after carbon tetrachloride, while a certain percentage was found in the chenopodium and the thymol cases (Table IV). The stools were screened very carefully through an 80-mesh to the square inch screen. Microscopic controls were performed at least 48 hours after treatment. If re-examination resulted positive, subsequent treatments were given at intervals of 4 to 5 days. The direct smear examinations of the stools were always supplemented with concentration and cultural methods.

Table I shows the number of cases treated with different doses of carbon tetrachloride, with chenopodium, and with thymol, the number of treatments, number and percentage of cures, and number and percentage of failures. It will be seen that all the way through carbon tetrachloride is superior to the other drugs. Carbon tetrachloride in doses of 1 c.c. per 5·5 kg., 7 kg., and 10 kg. body weight, and mixed with magnesium sulphate cured 55, 52, 34 and 53 per cent. respectively; chenopodium, 40 per cent.; thymol, 26·3 per cent., with the first treatments, and 73, 75, 61, 67, 33 and 20 per cent. respectively with the second treatments. The only objection to carbon tetrachloride noticed was that it produces dizziness, vomiting, and a varying degree of debilitation. These symptoms, however, are practically nil when the drug is given in doses of 1 c.c. to 10 kg. body weight and in combination with magnesium sulphate as described. The carbon tetrachloride must be repurified C.P. to be safe. Ill effects were not noted either with chenopodium or with thymol.

TABLE I.—THE CURATIVE EFFECT OF CARBON TETRACHLORIDE, CHENOPODIUM AND THYMOL.

Drugs used and dose.	CCl_4 1 c.c. for every 5·5 kg. body-weight	CCl_4 1 c.c. for 7 kg. body-weight	CCl_4 1 c.c. 10 kg. body-weight	CCl_4 and Mag. Sulp.	Chenopodium 3·0 c.c.	Thymo 2·6 grm.

Percentage positive	—	—	—	—	100	100

Thymol in small pieces has been found many times in the stools, and in one case two pieces, practically the size and shape of the capsules administered, were found during screening. The thymol was well powdered and freshly put into capsules. It seems, therefore, that, due to some action of the gastric or intestinal contents, the drug failed to dissolve, and that it even fused.

Table II shows the number of cases given two treatments, the drugs used, the total number of worms recovered with two treatments, the number recovered with the first treatment, the number recovered with the second treatment, and the percentage of worms recovered by the first treatment. A higher percentage of worms was recovered by the first treatment with carbon tetrachloride than after treatment with the other drugs. Carbon tetrachloride 1 c.c. for 5·5 kg., 7 kg., and 10 kg. of body weight, and mixed with magnesium sulphate, chenopodium, and thymol removed 97, 96, 91, 93, 89·5 and 74·1 per cent. respectively by the first treatment.

TABLE II.—PERCENTAGE OF WORMS REMOVED BY THE FIRST TREATMENT.

Drugs and dosage.	CCl_4 1 c.c. per 5·5 kg. body-weight.	CCl_4 1 c.c. per 7 kg. body-weight	CCl_4 1 c.c. per 10 kg. body-weight	CCl_4 and magnesium sulphate	Chenopodium 3 c.c.	Thymol 2·6 grm.
Number given two treatments	33	10	17	10	23	20
Total removed, two treatments	1421	335	291	248	1688	666
Total removed by first treatment	1381	324	266	231	1518	494
Percentage	97·0	96·5	91·0	93·0	89·5	74·1

Table III shows the vulnerability of species and sex by the use of the different drugs, computed on worm classifications on cases given two treatments. Carbon tetrachloride 1 c.c. to 7 kg. body weight removed 95·2 per cent. of ankylostomes and 98·8 per cent. of necators, by the first treatment, chenopodium 3 c.c. removed 72 per cent. of ankylostomes and 91 per cent. of necators. Thymol removed 64·3 per cent. of ankylostomes and 74·8 per cent. of necators. To all the drugs used the necators are more susceptible than ankylostomes and the males more than females.

TABLE III.—THE VULNERABILITY OF SPECIES AND SEX TO THE DRUGS USED.

Drug used and dose	Number cases		First treatment Ankylostome Male	First treatment Ankylostome Female	First treatment Necator Male	First treatment Necator Female	Second treatment Ankylostome Male	Second treatment Ankylostome Female	Second treatment Necator Male	Second treatment Necator Female	Total
CCl_4 1 c.c. per 7 kg. body weight	4	Number worms by sex	187	183	98	132	8	11	1	2	6
		Per cent. by sex	96	94·4	99	98·5	4	5·6	1	1·5	—
		Number worms by species	370		230		19		3		—
		Percentage by species	95·2		98·8		4·8		1·2		—
Chenopodium 3 c.c.	10	Number worms by sex	58	49	401	380	15	26	31	47	1,0
		Percentage by sex	79·5	65·4	92·9	89	20·5	34·6	7·1	11	—
		Number worms by species	107		781		41		78		—
		Percentage by sex	72		91		28		9		—
Thymol 2·3 grm.	20	Number worms by sex	17	10	163	304	7	8	47	110	6
		Percentage by sex	70·8	55·5	77·6	73·4	29·2	44·5	22·4	26·6	—
		Number worms by species	27		467		15		157		—
		Percentage by sex	64·3		74·8		35·7		25·2		—

Table IV shows the discharge of worms the first 24 hours and the second 24 hours after treatment. Worms were not recovered in the third 24-hour stools; with carbon tetrachloride 0·3 were recovered in the second 24 hours, while with chenopodium and thymol 8·5 and 4 per cent. respectively were recovered. This seems to show that carbon tetrachloride is rapid in its effect in that practically no worm was passed in the second 24 hours after treatment.

TABLE IV.—THE DISCHARGE OF WORMS DURING THE FIRST 24 HOURS AND DURING THE SECOND 24 HOURS AFTER TREATMENT (FIRST TREATMENT).

Drug	Number of cases	Total worms	First 24 hours	Second 24 hours	Percentage worms in second
CCl_4 1 c.c. for 7 kg. body-weight	8	355	352	1	0
Chenopodium 3 c.c.	13	717	656	61	8
Thymol 2·6 grm.	20	434	417	17	4

SUMMARY.

(1) Carbon tetrachloride 1 c.c. for every 5·5 kg of weight was given to 200 cases once, curing 9 per cent.; to 45 cases twice, curing 73 per cent to 8 three times, curing 50 per cent. Carbon tetrachloride 1 c.c. for every 7 kg. body weight was given to 44 cases once, curing 52 per cent.; to 1 cases twice, curing 75 per cent. Carbon tetrachloride 1 c.c. for every 10 kg. body weight was given to 38 cases once, curing 34 per cent.; to 1 cases twice, curing 61 per cent. Carbon tetrachloride 4 c.c. as maximum adult dose mixed with saturated solution of magnesium sulphate was given to 43 cases once, curing 53·5 per cent.; to 1 cases twice, curing 67 per cent.

(2) Chenopodium in the dose of 3 c.c. was given to 57 cases once, curing 40 per cent.; to 21 cases twice, curing 33 per cent.; and to 8 cases three times, curing 87 per cent.

(3) Thymol, 2·6 gm., was given to 38 cases once, curing 26·3 per cent.; to 15 cases twice, curing 20 per cent.; to 10 cases three times, curing 50 per cent.; to 4 cases four times, curing none.

(4) Carbon tetrachloride 1 c.c. for every 5·5 kg body weight removed by the first treatment 97 per cent. of worms (from those given two treatments) 1 c.c. for every 7 kg., 96·5 per cent.; 1 c.c. for every 10 kg., 91 per cent.; carbon tetrachloride and magnesium sulphate, 93 per cent.; chenopodium 3 c.c. 89·5 per cent., and thymol 2·6 kg. 74·1 per cent.

(5) Carbon tetrachloride 1 c.c. for every 7 kg. body weight removed 95·2 per cent. of ankylostomes and 98·8 per cent. of necators with the first treatment; chenopodium, 72 per cent. of ankylostomes and 91 per cent. of necators; thymol, 64·3 per cent. of ankylostomes and 74·8 per cent. of necators.

(6) Carbon tetrachloride 1 c.c. for every 7 kg. body weight removed 96 per cent. of male ankylostomes and 99 per cent. of male necators; chenopodium 79·5 per cent. of male of ankylostomes, 92·9 per cent. of male necators; thymol, 70·8 per cent. of male ankylostomes, 77·6 per cent. of male necators. Carbon tetrachloride removed 94·4 per cent. of female ankylostomes and 98·5 per cent. female necators; chenopodium 65·4 per cent. of female ankylostomes, 89 per cent. of female necators; thymol, 55·5 per cent. of female ankylostomes and 73·4 per cent. of female necators.

(7) Apparently carbon tetrachloride is more rapid in its action than the other drugs.

SUBACUTE INGUINAL PORADENITIS, OR CLIMATIC BUBO.

By E. P. DE BELLARD.

Medical Director and Chief Surgeon, Beacon-Sun and La Paz Hospitals, Valera, Venezuela.

THE present study is based on 22 cases of poradenitis that I have treated at the Beacon-Sun Hospital in the course of the past four years. All, except one, occurred in Americans who had resided in Venezuela for a period that varied between two weeks and two years.

This disease has been known for many years under two different names, and it is only very recently that the majority of authors have become convinced that the two are the same identical pathologic process, in the tropics as climatic or tropical bubo, and in Europe under a variety of denominations: strumous bubo, subacute simple adenitis with intraganglionar purulent foci, idiopathic adenitis, subacute inguinal lymphogranulomatosis, adenogenous ulcer, and fourth venereal disease, this confusion in nomenclature being due to differing opinions regarding its ætiology. To Professor Favre, of Lyon, and his pupil, Phylactos, is due the credit of having first called attention to the identity of the tropical and the European diseases.

HISTORY.

Bodnar [1] and Ruber [2] in 1879 were pioneers in drawing a distinction between the bubo they observed in the tropics and the group of common venereal, tubercular, and simple adenitis, and believed it to be a manifestation of malaria. The publication of their observations was followed by those of Segard [3], Guerin [4], Cantlie [5], Lesueur-Florent [6], and Blanc [7]; Cobb and Simpson [8] observed similar cases in India, and believed them to be cases of *pestis minor*, while Ruge [9] treated a small epidemic of the disease on board German war vessels anchored off Zanzibar. Once attention was called to the new malady it was soon reported from nearly all tropical countries. On the other hand, in Europe it was first reported by Chassaignac [10], and later by Velpeau [11], who pointed out the difference between the pathologic findings in the different forms of adenitis, but it was Nélaton [12], and after him his pupil, L'Hardy [13], who first gave a complete description of the disease in Europe, separated it from the group of tubercular adenitis which it so closely resembles at times, called attention to the difficulty of determining the portal of infection, noticed the suspicious presence in some cases of herpetiform genital lesions, insinuated the possibility of this being a transmissible venereal disease, and proposed the name of *simple subacute adenitis with intraganglionar purulent foci*. These interesting studies were followed by those of Lejars [14], Marion et Gandy [15], Pigeon et Tanton [16], and Brault [17]. In 1913 Durand, Nicolas et Favre [18] demonstrated the prevalence of the malady in France, gave it the name of *subacute inguinal lymphogranulomatosis*, and described the initial herpetiform lesion later called by Bory [19] *lymphogranulomatous chancre*. I believe that the thesis of Phylactos [20] practically dispels all doubts about the identity of the two diseases. Desteéfano and Vaccarezza [21] report twelve cases from Buenos Aires and propose the name of *subacute inguinal poradenitis*, which I have adopted in this article because I consider it less cumbersome than others and fairly well descriptive of the disease. The first published report of the prevalence of tropical bubo in Venezuela was by me in 1922 [22]. Comparatively little is found in the medical literature of the United States concerning poradenitis: however, Smith [24], Treilby [25], Phillips [26], Barlow [27], and a few others have given us interesting accounts of cases.

CLINICAL STUDY.

Subacute inguinal poradenitis is a disease of wide geographic distribution, found in all tropical countries and perhaps in many of those of the temperate zone, possibly unrecognized, masquerading under the guise of tubercular inguinal adenitis. In Venezuela it affects mostly young men of the Caucasian race recently arrived in the tropics, whilst women and children of all races are immune. Its most outstanding clinical sign is the presence in the inguinocrural region of a tumour involving several of the lymphatic glands of these groups, which at operation are found to contain numerous small abscesses scattered throughout the whole gland tissue; it is further characterized by extensive periadenitis, a tendency to sinus formation and chronic suppuration, while only mild general symptoms accompany the imposing local syndrome.

Nicolas and Favre were the first to insist on the

genital origin of the infection, and described the initial lesion or *poradenic microchancre*, which affects a variety of forms; most frequently it assumes the appearance of a small, painless, shallow, non-infiltrated ulcerated herpetiform lesion. However, it is but seldom discovered in the cases of poradenitis, be that due to the insignificance of the lesion itself and the fact that it gives rise to no symptoms, or to its evanescent character. I have discovered a typical poradenic chancre in only two of my cases and in neither was its presence suspected by the patient. Nearly all cases of poradenitis that I have seen were in men who had a long prepuce or phimosis and who kept their genitals very unclean, and under these circumstances it is very easy to overlook a microchancre situated at the balano-preputial fold which is its favourite location. But it is possible that the virus may utilize for its accession some other pre-existing venereal lesion.

The portal of entry would seem to be unquestionably somewhere in the genital zone or its immediate vicinity; the usual location of the original bubo, affecting as it does the supero-internal group of inguinal glands, supports this view. However, in the majority of instances it is impossible to locate definitely the point of inoculation, and the most painstaking search will fail to reveal any lesion whatsoever, the bubo being the first evidence of the disease noticed.

That poradenitis is usually of venereal origin seems most probable; that it is always so is questionable, as I have observed it in a young man who had never had sexual intercourse, and Destéfano and Vaccarezza report a similar instance. In two other of my cases the disease made its appearance several months after the last intercourse, so these could not be considered of venereal origin unless we admit the supposition that the virus may be contracted and then remain latent for long periods of time. Again, the disease behaves most unlike the other true venereal diseases: it does not attack women, and, with rare exceptions, spares natives.

Judging by several seemingly clear-cut observations, it might be deduced that the organism producing poradenitis is harboured in the vagina of filthy women and in the smegma of men of unclean personal habits, a long prepuce greatly favouring their habitat, and that it is implanted in the lymphatic mesh and thence invades the inguino-crural nodes through some abrasion in the genital zone inflicted during coitus or through rubbing or friction in the neighbourhood of the pudenda; the infection would be especially favoured if this region were moist and macerated by heat and sweat such as attends violent exercise, long horseback rides, or driving a truck during the hottest season of the year over rough roads.

In my cases poradenitis always started in the supero-internal group of inguinal lymphatic glands on one side, and affected the left more often than the right (64 per cent.), eventually becoming bilateral in 22 per cent. of the cases. In 88 per cent. the inguinal glands alone were involved, but in 22 per cent. the crural glands were later affected. As a rule only the superficial groups of glands are attacked, as in but two of my series did it extend to the deep ones. On the other hand, involvement of the iliac lymph nodes is almost a constant phenomenon. Even when the disease may be properly called unilateral the glands of the opposite side are frequently found to be slightly enlarged and somewhat sensitive to pressure.

The observation in other gland-groups than the inguino-crural of lesions resembling those of poradenitis are extremely rare and have been reported in only half a dozen instances by Ravaut, Boulard and Rabeau, Nicolas and Favre, and Nélaton.

Pathology.

In the course of poradenectomies I have observed all the stages in the evolution of the disease. The first pathologic evidence refers to a stage of congestion with some hypertrophy; the gland assumes a purplish colour and shows abnormal vascularization, and on section presents a granular appearance, diffuse studding with punctiform hæmorrhages and minute areas of grayish infiltration showing early abscess formation especially towards the centre of the gland, while the cortical area is still more or less free. The capsule appears somewhat thickened, surrounded by a delicate meshwork of fine adhesions. Usually no matter how early the case is operated on, not only the main gland affected, but to a variable degree the neighbouring lymph nodes also show these changes. At a later stage the periglandular adhesions have become very strong and extensive, anchoring the gland firmly to its neighbours and to the surrounding tissues. The gland has increased to several times its normal size, and its surface, as well as the central ganglionar mass, are studded with numerous abscesses ranging in size from microscopic proportions to that of a pea. These abscesses are isolated from one another, separated by a zone of apparently healthy parenchymatous tissue, and contain thick, greenish or yellowish, viscid, odourless pus. When the thickened and tough capsule is stripped off, the surface of the lymph node appears roughly granular and is sometimes found covered with a greenish fibrinoplastic exudate which adheres tenaciously to the gland tissue. In the advanced stage of the fully developed disease the tumour is composed of a large conglomerate of agglutinated glands involving several, sometimes all, the glands of the inguinal and crural groups, firmly adherent and fused into one mass; this is surrounded by an atmosphere of extremely tough adhesions which anchor it immovably to all neighbouring structures including not rarely the spermatic cord above and the sheath of the femoral vessels below. In the meshes of this periadenitis are found purulent and hæmorrhagic foci, separate and distinct from each other in the beginning, but later coalescing to form more important collections. The lymph node itself will be found to contain numerous small abscesses

and a large one located centrally, formed by the coalescence of several contiguous purulent foci, and to be discharging its contents through a minute sinus. In neglected cases several of these larger abscesses may have formed, each discharging pus through its own fistula. The parenchyma surrounding the abscesses is the seat of hæmorrhagic infiltration and becomes very friable. The skin covering the poradenic tumour adheres to the underlying mass, sometimes assuming an œdematous, tense, shiny appearance and a characteristic reddish-violet hue.

Rarely, the poradenic gland presents a special and very different aspect: it feels firm, shows no miliary abscesses detectable with the naked eye, and on section presents a perfectly smooth, homogeneous surface of light pink colour and a velvety feel. This peculiar appearance, already noted by Favre, has been very aptly termed by him " chair de poisson," on account of its close resemblance to fish meat; the excised glands in my case No. xxi presented the typical " chair de poisson " lesions. Histologic sections of these glands show the typical stellate abscesses, but they are all of microscopic size.

The curious periglandular cords first mentioned by Brault, and later observed by Favre, have been encountered in four cases: in one it was evidently an enlarged, indurated lymphatic tract twice as thick as a goose-quill, which joined together three adjacent diseased lymph nodes; in another it was a thick cord found crossing the operative field on a line parallel to Poupart's ligament, and which resembled in size and appearance the spermatic cord; in the other two cases they were strong fibrous cords formed by the periadenitic adhesions.

The material obtained at operation in 14 cases was submitted to our Pathologist, Dr. C. Uribe, for study in our laboratory.[1] Briefly, the lesions characteristic of poradenitis consist of an active vascularization, a diffuse infiltration of the lymphoid and periadenitic tissue with plasma cells, with here and there a giant cell, the formation of numerous abscesses of stellate shape, an occasional gummatous lesion very similar in its morphology to those found in lymphatic tuberculosis, and the constant finding of vascular lesions such as endarteritis obliterans, thrombosis, rupture of blood-vessels and hæmorrhage into the lymphoid tissue of the node and into the periadenitic inflammatory zone. Certain so-called *chromatic bodies*, both extra and intracellular, are constantly found with the macrophages on the inner aspect of the epithelioid wall lining the stellate abscesses as well as among those which are free in the contents of the abscess. Our pathologist thinks that they may possibly bear some ætiologic relationship to the disease, but other observers consider them to be remnants of disintegrated polynuclear cells. These *chromatic bodies* show well after staining with Giemsa, or still better, with a combination of Manson's boracic blue and eosin.

[1] For a full discussion of laboratory findings, experiments and case reports, the reader is referred to a previous monograph (see Bibliography, No. 23).

Ætiology.

Several diseases have been accused by different authors of producing the lesions of poradenitis: syphilis, malaria, plague, tuberculosis, gastro-intestinal infections, &c., but careful clinical and laboratory studies carried out by many competent observers, and which our own experiments and laboratory work have only confirmed, have proven these assumptions erroneous.

The ætiologic cause of poradenitis has not been determined. The possibility that the above described *chromatic bodies* may yet be proved to be protozoal organisms playing a pathogenic rôle in this disease is very doubtful. The pus of the closed buboes has constantly been found to be sterile, and slides made with it and with necrotic gland tissue and stained by diverse methods, as well as all cultures made in the usual and special media, have always failed to show the presence of any suspicious organisms. Inoculation experiments were carried out with the material obtained in most of my cases; white rats, guinea-pigs, rabbits, and two *Cebus* monkeys were utilized, and a fresh emulsion of poradenic gland tissue in normal saline was inoculated into the mucous membrane of the prepuce or vagina, intraperitoneally, subcutaneously or intratesticularly. With the exception of three encouraging instances, all our experiments gave us negative results. First: with material obtained from Case xvi, one rabbit, three white rats, and two guinea-pigs were inoculated; two weeks later one of the guinea-pigs showed a bilateral enlargement of the inguinal lymph nodes. While waiting for further developments the adenitis spontaneously disappeared within a few days. The other animals were unaffected. In the second instance, a *Cebus* monkey was inoculated into the prepuce with material obtained from Case xvii on September 6, 1924. By September 28 a tumour-like mass had developed near the root of the penis, firm to the touch and painless, while the inguinal glands on both sides were enlarged. October 14 the lesion on the penis is unchanged, the lymph nodes have increased in size, and the skin over them remains normal and free from adhesions. The largest was excised for histologic study. October 29: a node in the right groin had markedly increased in volume, becoming painful and firmly adherent to all surrounding tissues; the preputial mass had diminished in size and had become softer. After this date all the glands receded gradually, and by the end of November, three months after the inoculation, were normal again, the monkey's health in the meantime not having apparently suffered to an appreciable degree. Sections of the gland removed showed marked vascularization, infiltration with plasma cells, scattered micro-abscesses of stellate form, and the usual vascular lesions that characterize

human poradenitis, but no chromatic bodies were seen, and polymorphonuclear cells, abundant in the human cases, were rather scarce in the tissue examined.

(3) On August 25, 1925, a guinea-pig and a *Cebus* monkey were inoculated in the prepuce with an emulsion of fresh poradenic material collected at operation. The guinea-pig, kept under observation for three months, has remained perfectly well. The monkey showed no local reaction at the point of inoculation or elsewhere in the prepuce such as was observed in the first monkey experimented with, but on September 7 the inguinal glands on both sides were definitely enlarged. They gradually increased in size, and the mass on the left side became somewhat fixed to the surrounding tissues excepting the skin, which remained free from all adhesions to the underlying tumour. On October 3, four weeks after its appearance and six weeks after inoculation, the mass was removed. No definite inflammatory periadenitis was made out, but many fine, delicate adhesions were found lightly fixing the mass to its bed. The tumour consisted of a single, very much enlarged and deeply congested lymphatic node, which on section showed no visible abscesses, but numerous punctiform hæmorrhagic foci.

The mass in the right groin was not interfered with, but as occurs so frequently in human cases of poradenitis, the main focus once extirpated, the enlarged gland on the opposite side began receding at once and could not be palpated two weeks later.

Microscopic sections of the gland removed showed well marked generalized congestion, abnormal vascularization, and scattered hæmorrhages into the parenchyma, with very few foci of apparently incipient necrosis, but no abscesses and a total absence of both chromatic bodies and leucocytic infiltration. The capsule was definitely thickened, and the connective tissue apparently increased throughout the gland. The vascular lesions were the most prominent, and dominated the picture.

While no claim is advanced to having reproduced poradenitis in the monkey the foregoing experiments are at least encouraging and suggestive.

The able and important assistance and co-operation of Dr. C. Uribe, formerly our Pathologist, in carrying out the necessary experiments and laboratory work for the preparation of this study is here gratefully acknowledged.

Symptomatology.

The appearance of a mass in the groin accompanied by a feeling of tension and discomfort, are the first and often the only signs during several days, and the patient may even be able to follow his occupation, but soon other symptoms supervene, such as persistent anorexia with marked loss of weight, profound lassitude and fever, while the tumour becomes painful on walking, though painless at rest. The fever rises to 38° or 38·5° C., and affects the continuous type with marked morning remissions, or more frequently the intermitten with normal temperature in the morning and a evening rise. Rarely, a high temperature of th continuous type persists for many days, simulatin typhoid fever.

The duration of the fever is variable: it may di appear after three or four days, but more frequent it persists during the progressive stage of the disea and then drops to normal. But the fever may r appear at any moment, and this coincides with t extension of the pathologic process to other ly phatic glands in the same or in a distant zone. T blood-picture shows a mononucleosis of the lar cell type.

The poradenic tumour is of a wooden hardne firmly anchored to the surrounding structures, a on deep palpation elicits very little, if any, pa In nearly all cases the iliac lymphatic glands a found markedly enlarged, and at times to such extent that they form a mass as large as the o in the groin, but the pathologic process in the il nodes does not progress beyond the stage of infla matory congestion of the gland, and they ne break down, receding to normal *pari-passu* with improvement of the inguino-crural process. T skin glides freely over the tumour for several da but in the advanced stage becomes adherent to underlying mass, and when this occurs it may assumed that extensive suppuration has alrea taken place; at this period the palpating fin detects in the centre of the hard tumour a more less circular area of doughy or waxy softening p mitting indentation, and as the finger-tip sinks detects a firm ring surrounding the area of de seated softening. Eventually, a capillary fis forms, which discharges an insignificant amoun sero-pus and may close again in a day or two w out leaving a trace of its former location; this m be repeated several times before the fistula becon permanently established. Later, other fistu may form which drain different, isolated foci suppuration until the whole tumour may beco one necrotic mass discharging small amounts o sticky sero-pus through many sinuses. A fus of all suppurating foci such as occurs in other for of adenitis never takes place in poradenitis.

Resolution of a poradenic tumour which has progressed to the stage of extensive suppurat may take place, but the process is a very prolon one requiring months. The usual course leads fistulization and chronic suppuration. A charact istic of the discharging sinuses is the fact that borders show no evidences of inflammation *chancrellization*, the bordering skin appear normal. The amount of pus discharged is alw small, and after the first few days may be onl few drops in the 24 hours, but this suppuration apt to continue during many weeks or months. H ever, the patient once free from the acute sy ptoms of the disease, leaves his bed to lead for next few months the existence of semi-invalidi imposed by the essentially chronic course so char teristic of poradenitis.

Prognosis.

This is always good as regards life, but must always be guarded as to the duration of the disease. A poradenectomy or total excision of all glands involved is the only method which offers probabilities of a prompt cure, but even timely surgical treatment does not always prevent a recurrence in some other group of lymphatic glands. Left to itself, a well-developed case of poradenitis may take from six months to one year for complete recovery.

Treatment.

Ravaut claims to have used with success intravenous injections of Lugol's solution alternating with emetine. Emily uses intraganglionar instillations of a xylol iodoform and paraffin-oil mixture. Nicolas, Favre, Rost and Bory recommend radiotherapy in the early stages of the disease. In my experience all treatments, except a prompt radical operation, yield uncertain and unsatisfactory results. The operative treatment has been recommended by Favre, Gaté, Nicolás, Brault, Dugas, Chavanne, and others.

Obviously, simple incision, curettage and drainage of the main focus of suppuration cannot accomplish much in these cases and is not to be advised.

The operation of poradenectomy can be performed in the early stage of the disease under local anæsthesia, but general anæsthesia is to be preferred in advanced cases. All manipulations in the depths of the wound should be carried out with gentleness and care, as the tumour is not infrequently attached by firm adhesions to the femoral sheath, while the upper border of the mass is often found intimately attached to the structures forming the inguinal canal, and there is danger of lacerating the spermatic cord.

The largest tumour that I have extirpated (Case iii) weighed 92 grammes and measured 10 by 4 by 2·5 cm.

The enlarged iliac glands require no treatment, as the poradenic process affecting them recedes rapidly after extirpation of the inguinal tumour. In cases operated on early, before the involvement of many glands or the production of massive periadenitis, and in which suppuration is confined to the intraganglionar miliary abscesses, the wound may be sutured *in toto*, without drainage, being careful to suppress all dead space; in more advanced cases simple drainage must be supplied for the profuse lymphorrhœa which is sure to follow and last for several days. Healing by granulation in these cases is always slow, but especially so if any portion of the affected glands was overlooked at operation, which must be a thorough one if it is to succeed in shortening the duration of the disease; an overlooked poradenic focus will keep up suppuration and possibly act as a source of infection to other glands.

Incipient cases operated on early and closed without drainage are cured within 10 or 12 days. More advanced cases require from two to four or five weeks for complete healing, according to the size of the cavity left by the removal of the tumour. Secondary suturing after the lymphorrhœa has ceased materially hastens recovery.

Sequelæ.

The excision of a poradenic mass usually gives rise to an œdematous infiltration of the surrounding tissues with lymph, the extent varying in direct proportion to the number of glands extirpated, but it is generally confined (it has been so in all my cases) to the vicinity of the operative wound. This œdema progresses in extent for the first three or four days and then gradually recedes as the lymph finds new avenues of discharge and disappears in the course of ten to fifteen days. However, Chavanne, Ravaut, Pigeon et Tanton, Marion et Gandy, Gaté, Brouardel and Brault have reported cases of pseudo-elephantiasis of the genitals and lower extremities consecutive to the extirpation of the inguinal lymph nodes. This serious sequela has occurred weeks and even months after the operation and persisted for long periods of time, occasionally for life. This possibility, though remote, is a serious drawback to the operation, and should be clearly stated to the patient before its performance. The additional fact that it does not always insure against further extension of the disease to neighbouring glands or an invasion of the glands of the opposite side also militates against the operation, but until some other effective method of treatment is discovered, a radical poradenectomy must remain the method of choice. In spite of the risk involved, every one of the young men that I have treated preferred submitting to a radical operation that promised a quick cure rather than face the long and tedious period of semi-invalidism which entails the spontaneous evolution of poradenitis. The uniform success that I have had in my 18 operative cases has strengthened my conviction that every case of poradenitis should be operated on at once.

Conclusions.

Subacute inguinal poradenitis is an autonomous pathologic entity of unknown ætiology, distinct from all the other usual forms of adenitis but very closely resembling pathologically a tubercular adenopathy. In the tropics the disease attacks almost exclusively young men of the white race recently arrived from colder climates. It is endemic in certain zones, with occasional mildly epidemic exacerbations. These outbreaks seem to coincide with long periods of drought and extreme heat. A long prepuce and uncleanliness of the genitals strongly predispose to it. The disease is manifested by an adenitis of the inguino-crural glands, characterized by multiple intraganglionar purulent foci accompanied by periadenitic inflammatory lesions, of a hæmorrhagic and suppurative type, with the formation of dense and extensive periglandular adhesions.

All non-surgical treatments so far tried have failed to produce uniformly satisfactory results, besides entailing serious loss of time. Poradenectomy, or

the radical excision of all diseased glands, should be the treatment of election and constitutes the only procedure that promises a quick recovery.

A Preliminary Report on the Control of Trachoma in the Philippine Islands (H. Velarde, R. Villafranca and S. Luna-Orosa, *Bulletin of the Philippine Health Service*, April, 1925).—While the result of the survey in the public schools for 1925 seems to show that trachoma among school children in Manilla is now under control and is on the decrease, trachoma still remains to be a problem which needs the serious attention not only of the Health Service but of the whole medical profession. Another factor which adds to the seriousness of this problem is the possible and probable importation of more cases into the country, more particularly from China and Japan, on account of the great number of these people that come to the islands. It is, however, a relief to know that the Immigration Law of the United States protects the Philippine Islands to a certain extent from the danger. The cases usually found in the Philippine Islands are of the chronic benign type; there are usually no serious complications observed or sequelæ left. The disease is more frequent in the males than females, and is generally found between the ages of 10 and 20 years.

Epidemic Bulbar Poliomyelitis. Report of Six Cases with one Necropsy (J. McEachern, *Journal of the Amer. Med. Assoc.*, January 9, 1926).—In a peculiar epidemic of poliomyelitis of the bulbar type, the cases all presented the common clinical symptom of paralysis of the muscles of the upper respiratory tract. There was no coincident paralysis elsewhere. A striking feature of several cases was the presence of a white, frothy mucous in the nose and throat. In agreement with the generally recognized severity of bulbar poliomyelitis two of the patients died, and in the others the clinical picture was for a time very grave. The constant involvement of the muscles supplied by the eleventh nerve is most unusual. The dissociation between clinical and pathologic findings is well exemplified in the case studied at necropsy, the most intense reaction occurring in the cervical cord rather than in the medulla. Paralysis of the sphincter vesicæ, of ten days' duration, occurred in one of the cases described, which also well illustrates the widespread distribution of the lesions.

BUSINESS AND GENERAL.

1.—**The address of** THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE **is Messrs. Bale, Sons and Danielsson, Ltd., 83-91, Great Titchfield Street, London, W.1.**

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—**All literary communications should be addressed to the Editors.**

4.—**All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of** THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—**The Subscription, which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—**The Journal will be issued about the first and fifteenth of every month.**

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to** THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE **should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

BRONCHOMONILIASIS.

WITHIN the last twenty years it has been ascertained that affections of the bronchi and lungs may be definitely associated with the presence of fungi in the sputum, and to the various conditions so produced the name of bronchomycosis is now applied. Of these fungi the organisms known as monilias have contributed most frequently to the number of cases of bronchomycosis which have been recorded, producing the form of bronchomycosis known as bronchomonilias, but with increasing knowledge and experience of these fungi, recent investigations have shown that quite a variety of fungi belonging to different species, genera, families and orders may also be encountered in these bronchomycotic infections.

Bronchomoniliasis was first described by Castellani in Ceylon in 1905, and since then it has been met with by many investigators not only in tropical and sub-tropical, but also in temperate regions. Thus, cases have been described in France by Pinoy, in South Africa by Pijper, in West Africa by Macfie, in Egypt and the Sudan by Chalmers, MacDonald and Farah, in Italy by Jacono and by Castellani, Douglas and Thompson, in America by Johns, Baggs and by Picoff and Simon, while a thorough study of the disease in India has been made by Taraknath Sur. The monilias which produce bronchomoniliasis are comprised of fungi which are characterized by the sporophores being simple or sub-simple and producing by constriction at their extremities a chain of large lemon-shaped conidia often provided with a disjunction apparatus. It would seem, however, that there is at present a general tendency to extend the term monilia so as to include all the organisms of the genus *Oösporaceæ* Saccardo 1886, the vegetative body or thallus of which appears in the lesions in the tissues, i.e., in its parasitic life, as a mass of mycelial threads or free-budding forms, some of the mycelial filaments being long and branched and often presenting arthrospores. In cultures on the ordinary laboratory media, i.e., in their saprophytic life, they mostly consist of yeast-like, roundish or oval bodies, while mycelial filaments are usually scanty. An investigation of the bio-chemical characters of the monilias shows that they often ferment glucose and other carbohydrates with the production of gas, and on the basis of these characters the monilias may be classified into several groups. It may be pointed out that monilias which present the same biochemical characters may differ enormously as regards pathogenicity, some producing a severe infection when inoculated into the rabbit or guinea-pig, whilst others appear to be quite harmless. A critical study of the symptomatology of the cases of monilia infection shows that they may be differentiated into two types, severe and mild, although cases of intermediate severity may also occur. The *severe type* of infection closely simulates, and may be mistaken for, phthisis. There is emaciation, hectic fever, and hæmoptysis. Physical examination of the chest reveals the presence of patchy dulness with fine crepitations and pleural rubbings. Cases of this type often have a fatal ending. In the *mild type* there is no fever, the general condition remains good. The sputum

is mucopurulent and free from blood and is often scanty. Physical examination of the chest is negative or merely reveals the presence of a few râles. After lasting for some weeks or months resolution may occur spontaneously or the severe type of the disease may supervene.

The diagnosis of bronchomoniliasis is based on the results of examination of carefully collected sputum showing the presence of monilias and the absence of tubercle bacilli. The sputum should be collected in a sterile receptacle after thorough gargling with warm sterile water, and it should be examined immediately. Microscopic examination of such sputum may reveal the presence of roundish or oval yeast-like cells, often presenting a double contour, and sometimes a few mycelial threads, or it may be quite negative and the fungus can only be found by the employment of cultural methods, which should never be neglected. The mere presence of a monilia in the sputum, however, should never be considered sufficient to establish the diagnosis of a primary bronchomoniliasis. It has been shown that when a monilia has been discovered in a sputum properly collected and examined three possibilities exist. In the first place the monilia, as shown by animal inoculation, is non-virulent and non-pathogenic. In such conditions the organism merely lives saprophytically in the bronchi, constituting a *saprophytic moniliasis*. Secondly, the monilia, though virulent, may represent a secondary infection, in which case intravenous injection into rabbits causes death of the animal, but intrapulmonary injection does not produce any nodular pulmonary lesions and the animal dies from a general monilial septicæmia. This *secondary moniliasis* is comparatively common in advanced pulmonary tuberculosis. Lastly, the monilia is the cause of the broncho-alveolar lesions, when intra-pulmonary injection in the rabbit produces a characteristic nodular condition in the lungs. This condition constitutes *primary bronchomoniliasis*. Whatever the variety of monilia concerned in the production of bronchomoniliasis the treatment consists in the administration of potassium iodide in fairly large doses, together with the exhibition of balsamics, particularly creosote. Incipient cases respond well to this treatment and in them the prognosis is usually good; in advanced cases, on the other hand, the prognosis must be more reserved. Autogenous monilia vaccines are apt to be disappointing, being only very occasionally useful.

When a patient who is not in a very advanced stage of the malady does not respond satisfactorily to the iodide-creosote treatment, further investigations into the ætiology of the condition should be carried out, with a view to discovering the presence of mixed infection, since cases of true mixed infection, for instance, bronchomoniliasis and bronchospirochætosis and bronchomoniliasis and bronchoanaeromycosis have been encountered, and in such cases the response to treatment has been unsatisfactory and the prognosis rendered more serious.

F. E. T.

Annotations.

Studies of the Resistance of the Chicken to the Nematode Ascaridia perspicillum (C. A. Herrick, *American Journal of Hygiene*, January, 1925).—It seems evident from the data presented that as chickens increase in age they become more resistant to the development of the nematode parasite *Ascaridia perspicillum*. The parasites developing in resistant chickens were more variable in size than those developing in hosts with low resistance. Parasites in chickens over 100 days old were not able to make a growth of over 0·1 mm. during the first ten days, while those in five-day old hosts made a growth of over 5 mm. Parasites in heavily infested chickens made less growth than in lightly infested hosts. Although parasites could be transferred from old to young hosts, they could not be changed from one old host to another. This suggests that they become specifically adjusted to their host. Thymectomy and the prevention of the flow of bile into the intestine had no effect on the growth of the parasites. The serum of one cockerel, when injected into young chickens, was effective in making them more resistant to parasitism. Young chickens when injected with other adult chicken serum, were less affected by the parasites, but were no more resistant to their growth. The removal of large amounts of blood, by cardiac puncture, from adult chickens, made them less resistant to the growth of parasites.

Endemic Goitre in New Zealand and its Relation to the Soil-iodine. Studies from the University of Otago, N.Z. (Ch. E. Hercus, W. N. Benson and C. L. Carter, *The Journal of Hygiene*, December, 1925).—The incidence of goitre among school children in New Zealand has been determined by the examinations made by one of the authors and by the officers of the School Medical Service, of over 80,000 children. The proportion of men of military age who were unfitted for active service on account of goitre was ascertained during the examination of over 135,000 recruits by the Military Medical Boards in the years 1916-1918. Additional information has also been derived from hospital records, by the number of operations for goitre. The amount of iodine has been determined in nearly 500 samples of a number of waters from mineral springs and town supplies.

It has been proved that the following relation is approximately true throughout the Dominion, viz., percentage incidence of goitre among school children is equal 6 plus the quotient of 360 divided by the amount of iodine in ten million parts of soil so long as this does not exceed 50, assuming defined methods of medical examination and chemical analysis. Further, the relation between the average amount of iodine in the soil and the percentage of military recruits medically rejected on account of goitre is of the same general nature, the latter figure being about one-twentieth of the incidence

among school children, though this proportion must also be diminished in regions in which iodine is particularly abundant. Approximately, therefore, the incidence of the disease is inversely proportional to the amount of iodine in the soil. Further, where, though the incidence of goitre is low, the amount of iodine in the soil is abnormally low, it has been proved that it is present in the water supply in greater amounts than usual, and the daily intake of iodine among the inhabitants of such a district is thereby maintained. Further, regions in which the average amount of soil-iodine is low are also those in which goitre is most frequently seen amongst the domestic animals.

The hypothesis that goitre is caused by a deficiency of iodine in the diet has been fully sustained by the present investigation, and that a relation holds between the incidence of goitre and the distribution of geological formations in New Zealand, Switzerland and perhaps in other countries. The administration of small amounts of iodine weekly as a prophylactic treatment of school children has had fairly good results, but the best method of prophylaxis is thought to be the daily ingestion of minute amounts of iodine, obtained by the utilization for all culinary and table purposes of an iodized salt, in which one part of potassium iodide had been added to 200,000 of sodium chloride—the method which has been attended by such satisfactory results in Switzerland. This would afford the minimum amount of 0·005 mg. per day, which seems necessary for the functional requirements of the thyroid gland, while it would be far too small to have any ill effects in the production of hyperthyroidism.

The Production of Albuminuria by Renal Vasoconstriction in Animals and Man (I. Starr, *Journal of Experimental Medicine*, January 1, 1926).—These experiments show that transient albuminuria follows the infusion of small doses of adrenalin into rabbits, if prolonged over several minutes. Agents causing renal vasoconstriction also cause transient albuminuria in anæsthetized, eviscerated dogs. Cats eliminate albumin after having been frightened or enraged. The drug ephedrine, which commonly causes vasoconstriction in animals, has been tested in man. Transient albuminuria followed its administration in those cases in which signs of renal vasoconstriction appeared; it did not in those cases in which such signs were lacking. Evidence was obtained that ephedrine is not intrinsically injurious to the kidney. The observed facts may be explained by the conception that renal vasoconstriction causes increase in the duration and extent of the normal intermittent interruptions in the glomerular circulation. Permeability of the glomerular membranes is so increased by these lengthened interruptions that when blood-flow is re-established albumin escapes. It is believed that this conception may apply to those albuminurias in man which result from excessive muscular exercise or emotion or which are produced reflexly. It may explain the occurrence of albumin in the urine of normal people and in healthy laboratory animals; it may play a part in the explanation of the albuminuria which occurs after anæsthesia or in cardiac decompensation. Its possible relation to orthostatic albuminuria has been discussed.

Microbic Virulence and Host Susceptibility in Paratyphoid-enteritidis Infection of White Mice. The Relationship of Dosage to Mortality Rate, Survival Time and Cage Population (Ida W. Pritchett, Sc.D., *Journal of Experimental Medicine*, February 1, 1926).—Epidemics of mouse typhoid set up among the Rockefeller Institute strain of mice were studied over a period of six months. During this time the relationship of cage number of mouse typhoid bacilli to mortality, total population, and survival time was determined. A single virulence titration of the epidemic strain was made, and at the end of the experiment all survivors were examined for evidence of infection. The following conclusions may be drawn from the data presented. The available dosage of mouse typhoid bacilli varied directly with the mortality (plus at a time constance of six to eight days) and inversely with the survival time. The virulence of the epidemic strain appeared to be practically the same as that of the original stock culture. About 53·5 per cent. of the survivors of one epidemic and 68 per cent. of those in the other showed, at the end of the experiment, no signs of infection; the others had either specific blood agglutinins, or living bacteria in their hearts' blood, spleen-fæces, or gall-bladder. During the course of the epidemic, the original infecting strain (mouse typhoid type II—*Bacillus pestis caviæ*) was almost entirely replaced by an antigenically dissimilar strain (mouse typhoid type I—*B. enteritidis*) probably introduced through the inadvertent inclusion of fæcal carriers among the normal mice added as contacts.

The Development of Onchocerca volvulus in Simulium damnosum (D. B. Blacklock, *Annals of Trop. Med. and Parasitology*, February 11, 1926).—*Onchocerca volvulus* infection is common in the Konno district of the Protectorate of Sierra Leone; larvæ of this parasite were found in the skin of 45 per cent. of persons examined systematically. A definite relationship between diseases of the skin or diseases of the eyes and the infection with *O. volvulus* as judged by the presence of larvæ in the skin could not be established. *Simulium damnosum* is very prevalent in the hilly country, which is covered with bush and grass, and has numerous streams and rivers; the lesion inflicted on the skin by this species in biting is such as would dislodge the larvæ of *O. volvulus* in the skin. Dissection of wild insects showed: (*a*) In 780 dissections of the gut an infection 2·6 per cent. with larvæ morphologically identical with those of *O. volvulus*. (*b*) In 1,320 dissections of the thorax a larval infection of over 1 per cent. By allowing wild flies to feed on restricted and heavily-infected areas of

the skin the gut infection was raised to 80 per cent. in one experiment, and the thorax infection to nearly 82 per cent. in another experiment; the developing forms of *O. volvulus* were found in the thorax after the infecting feed up to the seventh, eighth and tenth days, after which period no insect survived.

Madura Foot (Mycetoma). The Black Variety in a Native American (J. A. Gammel, H. Miskdijan and H. S. Thatcher, *Archs. of Dermatology and Syphilology*, January, 1926).—Report is made of an infection with the granuloma maduromycosis (mycetoma) in a native American from Texas. This is the twenty-first case reported from the United States and the eleventh from Texas. The infection was of the black grain variety—the first thus far reported in a native American and the second black grain infection reported on the North American Continent. All attempts at animal inoculations were negative—using monkeys (*Macacus rhesus*), rabbits, guinea-pigs, white rats, white mice and pigeons. Cultural experiments thus far carried out lead one to classify the causative organism with the Madurella group (Brumpt), and because of its characteristics as a new species the authors term it *Madurella americana*. A detailed description will be published later.

Recklinghausen's Disease without Tumour Formation. Incomplete or Abortive Forms of the Disease (F. Wise and J. J. Eller, *Journal of the American Medical Association*, January 9, 1926).—The cutaneous manifestations of Recklinghausen's disease consist, in a certain group of cases described by the authors, of nothing more than widely scattered pigment spots irregularly distributed on the trunk, buttocks and thighs. They vary from a light yellow to a deep brown, and from pinhead-sized freckles to extensive areas, large enough to cover a buttock or a thigh, or a large area of the trunk. This tumourless variety of the affection is usually encountered in one or more children of a family in which either parent has a typical neurofibromatosis cutis, as originally described by Recklinghausen. However, a pigmentary eruption without tumours may also occur in adults. To this variety of Recklinghausen's disease the terms "incomplete" and "abortive" have been applied, suggesting the assumption that as the disease progresses, tumours eventually will make their appearance. The terms neurofibromatosis cutis or fibroma molloscum multiplex are applicable only to those cases in which tumours form a part of the clinical picture.

The Ætiology of Chronic Ulcerative Colitis. Experimental Studies with Suggestions for a More Rational Form of Treatment (J. A. Bargen and A. H. Logan, *Archives of Internal Medicine*, Dec. 15, 1925).—A Gram-positive diplococcus has been isolated in 80 per cent. of cases of chronic ulcerative colitis. This organism was obtained in pure culture from the early lesions, in an acute exacerbation of the disease, from the depths of chronic ulcers, and occasionally from distant foci elsewhere in the body. By the intravenous injection of the organism, lesions like those in human beings are produced in rabbits and dogs, the lesions in the latter approaching the chronic stage of the disease in human beings. The finding of this organism in distant foci and the production of acute lesions in the colon could account for the repeated exacerbations of the disease and the pathologic findings of layer on layer of the granulation and fibrous tissue, replacing the colon mucosa. From these studies, it would seem that hope of control of this disease lies in (1) removal of the distant foci of infection; (2) immunization in some form against the causative organisms; (3) local and topical application and irrigation; (4) the empiric use of drugs, such as tincture of iodine: (5) the administration of some absorbent like kaolin by mouth, and (6) a non-irritating yet generous diet.

Sporotrichosis in Man. Report of a Case (F. J. Burgess, *Archives of Dermatology and Syphilology*, November, 1925).—A case of sporotrichosis occurring in a patient in Montreal is reported. Apparently this case represents a somewhat unusual type of the disease, and probably is best described as a single sporotrichotic gumma. The causative fungus is believed to be *Sporotrichum beurmanni*, notwithstanding certain definite variations. Of interest is the slow response to potassium iodide, a drug that usually results in a relatively quick involution of these lesions. A six months' course of treatment with large doses of potassium iodide was necessary before complete recovery resulted. The observation that in tertiary syphilis with gummatous lesions extraordinary large doses of potassium iodide may be taken without causing any untoward general symptoms raises the question whether here, too, such a lesion may not be able, so to speak, to take care of equally large amounts of potassium iodide without showing symptoms of iodism.

The Present Status of Hexylresorcinol as an Internal Urinary Disinfectant (V. Leonard and Austin Wood, *Journal of the American Medical Association*, December 12, 1925).—The investigations that have led recently to the development of hexylresorcinol and its application as an internal urinary antiseptic were begun about 12 years ago. In the use of hexylresorcinol the best results will follow only the strict observance of four controlling factors, all of which bear a close relationship to considerations of surface tension: (1) the dosage must be adequate; (2) fluids must not be forced; (3) sodium bicarbonate is contra-indicated for the reason that it raises the surface tension of the urine, and, like large quantities of water, thereby robs the urine of its bactericidal properties. Hexylresorcinol is equally

efficacious in alkaline and in acid urine; (4) the course of treatment with this drug must be proficiently prolonged. Among the organisms commonly found in urinary tract infections, those which are most resistant to surface tension changes in the test-tube (colon group) are most resistant to the action of hexylresorcinol *in vivo*. Urinary infections by *B. coli* and related types ordinarily require from 60 to 90 days' continuous treatment with the drug. If combined with the usual local measures, the course of treatment will be shortened and the percentage of ultimate cures increased.

Effects of Spontaneous Disease on Organ Weights of Rabbits (Wade H. Brown, M.D., Louise Pearce, M.D., and Chester M. Van Allen, M.D., *Journal of Tropical Medicine*, February 1, 1926).—A group of 27 rabbits presenting clinical manifestations of disease of spontaneous origin was studied with a view to determining whether any relation could be detected between physical constitution as represented by organ weights and functional activity as measured by the efficiency of the reaction to disease. The results of the investigation are presented by the authors in tabular form and the values obtained are compared by means of graphs, with corresponding values for normal rabbits. It was found that animals that were the subjects of disease showed decided changes in the weights of nearly all organs, changes which appeared to be of functional origin in that the values obtained for organ weights and co-efficients of variation tended to conform in general with the efficiency of the reaction displayed by the various groups of animals into which the entire series was divided.

The Effect on Paramecia of Blood-serums, especially from Patients with Carcinoma (G. A. Daland, *Archives of Internal Medicine*, Dec. 15, 1925).—Paramecia, when mixed with human blood-serum, form vesicles, the rate of formation being an index of the lethality of the serum. No specific substance was found in the blood-serum of patients with carcinoma which affected the rate of vesicle formation in paramecia in any way different from normal serum. Sera from diseased persons may resemble those from normal subjects in their effects on paramecia, or their toxicity may be greater or less. Serum obtained at the time of menstruation is slightly more toxic than at other times. Sera differing in their effects on paramecia may be made to act similarly by altering their concentration. Diluted sera, sera containing haemoglobin or that have been heated, sera irradiated with ultra-violet light, and sera of patients who have just received Roentgen-ray therapy are all less toxic for paramecia than the control sera.

Creeping Eruption (J. L. Kirby-Smith, W. Dove, and G. F. White, *Archives of Dermatology and Syphilology*, February, 1926).—Skin infestations in man by larvæ of *Gastrophilus hypoderma* and other flies has been reported from various countries, and it has generally been supposed that creeping eruption was caused by such larvæ. It is now seen that different skin diseases have been diagnosed "creeping eruption." Some of these are fly larvæ infestations (myiasis), others are due to a nematode of the genus *Gnathostoma* (gnathosto-myiasis), still another disease is caused by a different nematode. For the latter disease the authors have chosen the name "creeping eruption," leaving it to those studying the other creeping diseases to choose suitable names for them. It is this disease that is discussed in the present paper. The cause of creeping eruption is a nematode larva approximately one-fiftieth of an inch in length and one twelve-hundredth of an inch in breadth. It was recovered from each of five excisions, representing four patients and as many different localities. More than 200 excisions were made, and of these forty-eight were sectioned serially, making more than 40,000 sections. The causal nematode is reported here for the first time and described under the name *Agamonematodum migrans*. Some persons are more susceptible to infection than others. Whites are more susceptible than negroes. Infection occurs more often in children than in adults, and are most frequent during the summer following rainy weather. More cases occur during the vacation period of school children. Cases in persons most extensively infestated have originated underneath buildings when men at work were wet with perspiration and were in contact with the damp, sandy soil. Minor infections have often occurred in children playing in low areas, where apparently surface drainage had disseminated the parasites. No definite conclusion can be drawn regarding the host of the adult of the nematode parasite. The origin of some cases in proximity with sewage disposal suggests a possible relationship with intestinal worms of man, while other cases have originated at points distant from such likely sources of contamination. The evidence tends to indicate that rats might be the normal host of the adult worm. Poultry, cats, dogs and other animals may possibly be concerned. That insects are concerned in the transmission of the disease is possible. The inability to locate the parasite definitely has much to do with the difficulty in treatment. When the parasite has invaded the sole or the palm, the difficulty is increased. Ethyl acetate applied on cotton or gauze or used in a flexible collodion has been effective in many cases. Refrigeration with ethyl chlorid, carbon dioxid snow, or crushed ice with salt has been used successfully.

Ankylostomiasis among the Troops in the Dehra Dun (G. Covell, *Indian Journal of Medical Research*, January, 1926).—Results of a hookworm survey of the troops in Dehra Dun, 1925, are detailed. The Gurkha troops are very heavily infested, the percentage of the infestation among them

being twice as high as among the R.A. gunners and drivers recruited in the Punjab. It is suggested that a hookworm survey of all Indian troops be carried out as a preliminary to mass treatment of infested units. Clayton Lane's method of direct centrifugal flotation is recommended as being rapid, accurate, and easily carried out. It is also suggested that beta-naphthol would be the most suitable drug for mass treatment, and that a course of treatment be given two months after the end of the rains, and repeated before the ensuing monsoon.

On the Variation in amount of Soluble Protein contained in Old Broth Cultures of Bacillus typhosus (J. W. Cornwall, *Indian Journal of Medical Research*, January, 1926).—The amount of soluble protein in broth cultures of *B. typhosus* rises continuously to a maximum, which is reached after seven to twelve weeks incubation and then falls again. This protein is derived from the solution parts of the bodies of dead bacilli. Individual bacilli do not probably live long when they cannot obtain sufficient nutriment to enable them to divide. Owing to local variations in the concentration of nutriment in a broth culture bacilli are continually dying, while reproduction is as continually going on. As the concentration of nutriment falls, the generation time lengthens. The rise in the soluble protein curve indicates that a larger amount of protein derived from solution of bacterial bodies is being added to the fluid than is being abstracted by degradation of protein. The fall in the soluble protein curve indicates that degradation of protein by hydrolysis is proceeding more rapidly than protein is being added by solution of bacterial bodies.

The Healing of Gastric Ulcers (B. B. Crohn, S. Weiskopf, and P. W. Aschner, *Archives of Internal Medicine*, February 15, 1926).—In two cases in which partial gastrectomy was performed for gastric ulcer, operation was timed to take place at the end of a course of preliminary medical treatment. The specimens removed showed these ulcers in the last stage of healing. In one case Roentgen-ray examination just before operation showed the disappearance of the niche that had been present. So-called "essential gastric hæmorrhage" cases, if operated on soon after the hæmorrhage, may show negative findings; if followed over a course of years they may eventually be demonstrated to be true ulcer cases. It is suggested that the negative findings at the first operation are due to the rapid healing of the ulcer after hæmorrhage. The rapid regression of ulcers in the intermission period will explain many cases of negative findings at exploratory laparotomy in cases with a suggestive ulcer history. In a series of such cases in which operation was done at a later date during a recurrence of the symptoms, the patient showed definite ulcer. The failure to demonstrate the lesion of a gastric or duodenal ulcer at exploratory laparotomy may therefore be due, at times, to the fact that the operation is carried out at a period in the life-cycle of an acute ulcer when rapid regression and healing have obliterated the ulcer crater and made the lesion impossible of discernment.

Current Literature.

Bulletin de la Societe de Pathologie Exotique, November 11, 1925.

The Intestinal Parasites in Natives of the Military Colonial Corps in France. Treatment and Prophylaxis (J. Emily).—Examination was made of troops of three different corps, i.e., Indo-Chinese, Malagash and Senegalese. The total number of examinations was 2,987, of which 906 were Indo-Chinese, 1,206 Malagash and 875 Senegalese. The percentages of those harbouring parasites were as follows: 88·96, 78·35 and 67·08 respectively. Thymol and tetrachloride were both efficacious in treatment. Measures will be taken to examine and treat all colonial natives on their arrival in France. The usual methods of prophylaxis are recommended.

Spirochætosis of Fowls in Greece (M. Stylapanopoulo).—This affection has never previously been reported in Greece. It occurred in epizootic form last summer in a number of fowl-houses in the neighbourhood of Athens. Both young and old animals were attacked and the rate of mortality was high. The affected animals cluster together, their feathers are ruffled and their combs are pale. They refuse all nourishment, but show marked polydipsia. There is very intense, greenish diarrhœa. They rapidly become thin, and, if the symptoms do not ameliorate, the animals die in a state of coma in about four to five days. At autopsy the liver is enlarged and there is fatty degeneration. The pericardium is slightly inflamed and contains a liquid exudate which coagulates on exposure to air. Numerous spirochætes are found in the blood, after staining with gentian-violet or Giemsa's stain. The malady has been transferred experimentally from a hen to a cockerel. The transmitting agent is *Argas reflexus*.

A Sanguicolous Spirochæte in a Domestic Dog (R. Bosselut).—The dog in this case came from Marengo, Algeria; there were signs of anæmia and the animal refused to eat. Temperature normal. Examination of blood showed numerous spirochætes, which the author has named *Spirochæte canina* nov. sp. Experiments to transmit the infection were negative. This is claimed to be the first case in which spirochætes have been found in domestic dogs.

Extraperitoneal Amœbic Abscess Simulating Appendicitis (Mme. A. Panayatotou).—The patient, aged 40 years, entered the hospital at Alexandria to be operated on for appendicitis. When the incision was made in the wall of the abdomen

large amount of pus extending to the right iliac was found, while the appendix was quite normal. Microscopic examination of the pus showed numerous *Amœba histolytica*. The patient did well. Owing to the extra-intestinal localization of the amœbic abscess it was thought that other organs might be affected; there was no cough or expectoration and all the organs were normal. Examination of the stools showed dead amœbæ and cysts. Injections of emetin and stovarsol were given.

The Action of Quinine on the Schizonts of Plasmodium malariæ (H. G. S. Morin).—Five cases of quartan fever have been closely watched in the hospitals of Marseilles, in order to follow the progress of the disappearance of the parasite under the action of the prescribed quinine treatment. *P. malariæ* is a particularly good material for such a study on account of the richness of its evolutive polymorphism. In three of the cases it took more than forty-eight hours for the parasites to disappear from the patient's blood; from the seventy-second hour there was less than one parasite per 200 fields, and from the fourth day the examinations were constantly negative. In the other two cases the parasites became very rare in less than twenty-four hours. When the patient is simply kept in bed the infection diminishes slowly but surely. The beginning of quinine treatment is marked by an immediate diminution in the number of parasites, and the larger the dose employed the quicker the disappearance. The cure of quartan fever is better brought about by prolonged treatment with quinine rather than by increase of the doses.

Blackwater Fever Syndrome during the Course of an Attack of Malaria (C. Vialette).—The interesting points in this case are, that it occurred in France, a country where blackwater fever is very exceptional, and during the period of the invasion of malaria in a patient who had never previously had the affection. It yielded to quinine therapy and did not recur under the influence of large doses.

An Epidemic of Yellow Fever in Liberia (G. Bouet).—Until recently Liberia was considered to be free from yellow fever. The epidemic broke out May 25, 1925; the first case was the cashier of an English navigation company, and the malady was diagnosed as cerebral malaria. Six other cases observed by the author are minutely described, all of which ended fatally, and they leave no doubt as to the nature of the disease. The author has observed the existence of *Stegomyia* in Liberia since 1918.

Note on Kala-azar of Honan, Central China (G. Villain), October 14, 1925.—The lower basin of the Yellow River, investigated by the author, is deeply infested with visceral leishmaniasis and constitutes a vast field of study for future experiments. The greatest handicap at present is the lack of laboratories and co-operation amongst medical men of the same nationality.

These observations have proved the innocuity of hepatic puncture in kala-azar; it did not cause any accidents in any of the patients treated, and it clearly showed typical leishmania in numbers sufficient to assure an almost immediate diagnosis. Nicolle's method was used. Tartro-bismuth is not reliable in this disease and often cause stomatitis. Antimony is the only active remedy, but it is not easy to carry out the necessary prolonged treatment by intravenous injections. Examination for the parasite in the stools, urine, sputum, &c., was negative, but in one case *Leishmania* were present in an old cutaneous ulcer. No definite conclusions are reached as to the transmission of Chinese leishmaniasis. Research for flagellates in the intestine of bed bugs gave negative result.

Contribution to the Posology of Stovarsol:—*Hebdomadal Doses of Stovarsol in Yaws* (G. Lefrou, October 14, 1925).—Very good results have been obtained in the treatment of yaws by stovarsol. The dose for adults was 2·5 to 3 gr. every seven days; it was well tolerated and caused no accidents. In some cases 4 to 5 gr. were given, according to the weight of the patient; larger doses cause febrile reactions and diarrhœa. All the patients increase in weight during treatment. For children a dose of 0·09 gr. per kg. can be given three times with a week's interval.

Reviews.

MANUAL OF EMERGENCIES, by J. Snowman, M.D. Price 10s. net. Published by John Bale, Sons and Danielsson, Ltd., 83/91, Gt. Titchfield Street, Oxford Street, London, W.1.

The second edition of this work now lies before us. The first edition was published in 1919 and was founded on Lenzmann's "Emergencies in Medical Practice," but the text was so entirely re-written and the subject matter was so extensively revised that the author claimed that the manual might fairly be treated as a new work, representing the teaching of standard British authorities on medical, surgical and obstetric emergencies. The second edition has not only been thoroughly revised, but has been issued in a new format, being published on thin paper, so as to reduce the volume of 371 pages to pocket size, so that it may be really at hand and available in all emergencies. The new material embodied in this edition includes the insulin treatment of diabetes, the serum treatment of botulism, quinidine sulphate in auricular fibrillation, the surgical treatment of angina pectoris, and Strogonoff's treatment for eclampsia. The practitioner, in whatever part of the world he may practise, will find this little volume extremely useful when faced with any of the emergencies he is liable to encounter. F. E. T.

REPORT TO THE SECRETARY OF STATE FOR THE COLONIES ON THE SANITARY CONDITION OF THE MINES AND MINING VILLAGES IN THE GOLD COAST COLONY AND ASHANTI. By Professor Sir William Simpson, C.M.G., M.D., F.R.C.P., D.P.H. Published by the Crown Agents for the Colonies. 1925.

This is a masterly report from a practised hand. It is divided into three parts. Part I contains a general account of the mines, the labour they employ, the causes of the high death-rate, and the remedial measures. Part II gives details relating to each mine and mining village. Part III contains Sir William Simpson's recommendations for the reorganization of the Public Health Department of the Gold Coast, and embodies much sound constructive criticism. Much reliable information is also contained in a number of appendices, which give temperature readings of the dry and wet bulbs, and results of dust samples in various mines; results of the examination of children's blood for malaria in several of the mine villages, and a summary of fæces examinations for helminthic infestations in hospital patients in Secondee and Coomassie and in latrines in mines and mine villages and in Accra. A number of elaborate plans and excellent photographs completes this model report.

F. E. T.

AN ELEMENTARY COURSE IN TROPICAL HYGIENE. Part II. By Mary G. Blacklock, M.B., B.Sc., D.T.M., lately Medical Officer, Sierra Leone, West Africa Medical Service. Preface by Andrew Balfour, C.B., C.M.G., M.B., B.Sc., F.R.C.P., Director, London School of Hygiene and Tropical Medicine.

We have already noticed Part I of this little work, which was meant for quite small children. Part II covers much the same ground, but is meant for somewhat older children, for students in training colleges, and for all those who, like nurses, health visitors and junior sanitary officials, require a knowledge of tropical hygiene written in simple non-technical language. There are also two supplementary chapters for older students, dealing respectively with inoculation and vaccination and the Public Health service. The opening chapter, on the value of hygiene, as Dr. Balfour points out, is well conceived, and is fitted to impress the youthful intelligence with the importance of paying attention to the laws of health, the arguments used being backed by illustrations of the successes achieved by hygiene in various parts of the world. The rest of the book is equally good, being concise, practical, accurate and to the point. In fact, the book must be judged a great success.

E. MERCK'S REPORT ON RECENT ADVANCES IN PHARMACEUTICAL CHEMISTRY AND THERAPEUTICS, 1917-1921, is the English dress in which Merck's *Jahresbrichte* for these years appears. Much useful information—both clinical and experimental—on new and important drugs is contained in this volume in an interesting form and rendered easily accessible. Bayer 205, silver, salvarsan, novarsenol and sanocrysin are drugs information about which will be welcome to our readers. The volume forms a convenient work of reference in handy form on the newer drugs, and there can be very few who cannot find something to interest or instruct them within its pages.

MEMORIA DE LA CAMPAÑA CONTRA EL PALUDISMO (1923-1924). (Report on the Campaign against Malaria, 1923-1924). Published by the Ministry of Health, Madrid, 1925.

This report, with its excellent maps and pictures, shows that though much is being done in the way of antimalarial work in Spain, much remains to be done, the malarial mortality in Caceres, the most severely infected province, having been 56·4 per 100,000 in 1923 and 43·3 per 100,000 in 1924. The central commission for antimalarial work is still continuing its successful labours.

THE WHITTINGHAM (W) STRAIN OF ARTIFICIALLY INDUCED MALARIA.

OBSERVATIONS MADE DURING THE TREATMENT OF GENERAL PARALYSIS AND TABES DORSALIS.

By A. R. GRANT, M.D.Aberd.,
Deputy Medical Superintendent,
AND
J. D. SILVERSTON, M.B., B.S.Durh.,
Senior Assistant Medical Officer, The County Mental Hospital, Whittingham, Preston.

THE treatment of general paralysis of the insane by malaria has been carried out in this hospital since July 21, 1922, and several observations on the value of this form of therapy in the disease have been made by us [4], [5], [6] from time to time. In this short note we wish to draw attention to some of the characteristics and behaviour of a strain of malaria which has now reached the fourth year of its existence and which still retains all its former potency and therapeutic value.

After preliminary work with strains of quartan, malignant tertian and simple tertian fevers we came to the conclusion that the latter was the most useful for our purpose, and so the birth of the Whittingham (W) strain took place on September 8, 1922, when a general paralytic was inoculated with blood from a patient who had contracted benign tertian malaria in India. From this host a long chain of cases of general paralysis and tabes has been infected, with the result that during the last forty-two months (three and a half years) the strain has been transmitted by direct subcutaneous inoculation through sixty generations, comprising over one hundred and fifty cases. Anopheline mosquitoes (*maculipennis* and *bifurcatus*) were infected with *Plasmodium vivax* by feeding them on patients in the twelfth and sixteenth passages of the strain. These mosquitoes were subsequently used to infect two of our cases, namely, one case of tabes dorsalis and one case of dementia præcox. Two more malarial stems of the simple tertian type were thus obtained, and as one originated in a non-syphilitic case of dementia præcox, we decided to name our strains of tertian malaria Whittingham (or W), W I and W II respectively. The strains W I and W II were allowed to die out; the former in a syphilitic host, was not further utilized, and the latter was stopped after several successful passages in non-syphilitic psychoses led us to believe that malaria was not a therapeutic measure of value in these cases. Again, with the introduction of the Pötzl [1] [10] method of inoculation, which in our hands has been successful with infected blood kept outside the body at 0° C. for varying periods up to seventy-two hours, we have enabled other hospitals in the country to commence and make observations on this form of treatment. The W strain in this way has been of service in the following general and mental hospitals: Leavesden, Exeter, Cardiff, Shrewsbury, Birmingham, Bradford, Cheddleton, Morningside, Cheadle Royal, York, Sunderland and the Liverpool School of Tropical Medicine.

Artificially induced malaria was obtained by injecting usually 2 c.c. of recently drawn venous blood from an infected source into the subcutaneous tissues of the host. As a general rule this operation was not followed by any constitutional or local reaction, but in a few cases fever (a temperature up to 101° F. on the second or third day), frontal headache and soreness at the seat of inoculation were encountered.

The incubation period, calculated from the date of inoculation to the day of appearance of parasites in the peripheral blood-stream, has been fairly constant, and although varying occasionally between six and twenty days, averaged from ten to twelve days throughout the period. In five cases, two inoculations were required before the fever and parasites appeared. These failures, after primary inoculation, were evenly spread over the "life" of the strain under review, and cannot be satisfactorily explained. Seizures of an epileptiform or apoplectiform nature have occurred during the incubation period, and on each of the three occasions we have considered it wise to prevent infection taking place and to reinoculate at a later date.

Ronald Ross [8] mentions that Ben-Harel has shown that in a series of blood inoculations of canaries with proteosoma, the red blood-cell count begins to diminish even as early as the day after the inoculation and long before the parasites become sufficiently numerous in the birds' peripheral blood to be detected. The decline was progressive day after day, until from one half to two millions of erythrocytes disappeared from the normal count (4·5 to 5 millions per c.mm.), when the parasites were discovered in the peripheral circulation. Daily erythrocyte counts were made on a series of seven male general paralytics before and after the inoculation and every day until *P. vivax* was demonstrated in the blood-films. The drop of blood in each case was taken from the finger two or three hours after the mid-day meal, and an average of three counts recorded. On the first day after inoculation there was a reduction in four cases, and an increase in the remainder; on the second day a reduction took place in five cases; on the third day in four counts, and on the fourth day a drop in five instances. In Case 4 there was an erythrocytosis for four days. On the sixth day and up to the day of appearance of parasites, the erythrocytes showed a diminution in all the cases. The lowest counts were recorded usually between the fifth and eighth days inclusive and averaged 3,100,000 cells; the reduction, however, was never progressive.

The commencement of the fever generally preceded the appearance of parasites in the peripheral circulation by one to four days; often parasites and fever coincided in the day of their appearance, while occasionally *P. vivax* forestalled every sign

of approaching fever by two to four days. The fever began usually with an increased pulse-rate and an elevation of temperature to 99° or 100° F., which mounted gradually for the next two or three days to a maximum of 103° or 105° F. before subsiding to the normal. This form of irregular pyrexia generally preceded and formed an introduction to the development of the malarial rigors whole period, but less so at the present moment as the pure tertian type is becoming more common. As many as three paroxysms of fever have taken place in the short space of twenty-four hours, but fortunately for the patient the occurrence is uncommon. (Figures 1 and 2 show typical quotidian and tertian fevers.)

In order to study more closely the changes

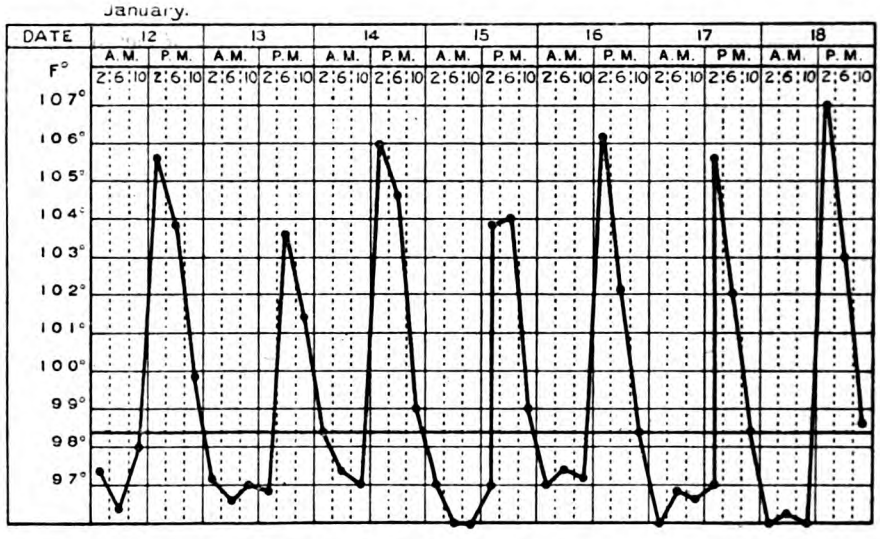

FIG. 1.—Typical quotidian curve.

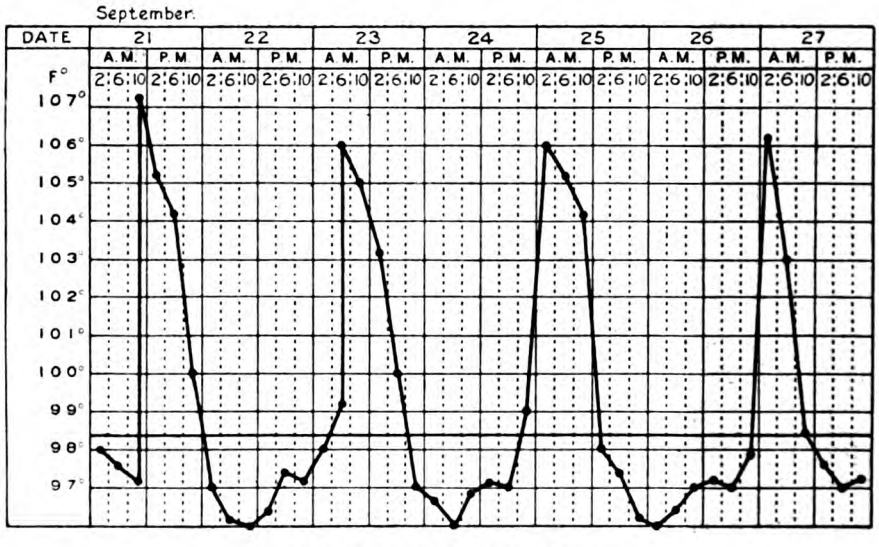

FIG. 2.—Typical tertian curve.

that invariably followed in their regular sequence. Rigors, although often slight in degree, appeared in some cases without any preliminary warning and waxed in intensity as the fever continued.

In the early and middle passages of the strain the types of fever in order of frequency were quotidian, a mixed type of tertian and quotidian, and pure tertian. The quotidian fever, or tertiana duplex, has appeared most frequently during the temperature during the various stages of paroxysm, a series of patients were put on "continuous" chart. That is from the date inoculation to the day of the disappearance parasites, the temperature, pulse- and respirati rate were taken at intervals of half an hour recorded. In this way several interesting obser tions were made. For instance, we found t quite often the temperature showed an eleva

of 2° to 3° F. above the subnormal interval range for an hour or two before the rigor actually took place, and less frequently, a rise of temperature ranging between 99° and 104° F. for a period of four to six hours suggested the same approaching phenomenon. In many cases the rigors were atypical and the rise of temperature or the stage of sweating were the only criteria that a paroxysm of malaria had taken place. On the whole, the stages were clearly cut and observed a certain proportion to each other; as a rule, the more pronounced the rigor the higher the fever and the more profuse the sweating. The maximum temperature of the paroxysm was reached in one half to three hours and varied in height with the number of the rigor; generally, the highest maximum was seen in the third, fourth or fifth, and ninth and tenth rigors, but this variation did not always hold good. The highest maximum temperatures recorded in the cases of the early stages of the strain ranged between 103·6° and 106·2° F. and at the present stage vary between 105° and 107·2° F. During the sweating stage the temperature gradually came down to normal, taking longer (from nine to seventeen hours) in the early than in the later rigors (from five to eight hours).

Stephens *et alia* [11], in 1921, studied the times of onset of one thousand paroxysms of simple tertian fever in mosquito-borne malaria, and came to the following conclusions:—

(*a*) Over 90 per cent. of the paroxysms occurred during the hours of activity (7 a.m. to 6.59 p.m.)

(*b*) The maximum number of paroxysms occurred at 2 p.m.

(*c*) Alteration of the period of activity by one hour, the result of the adoption of summer time, produced a corresponding alteration in the time of incidence of the paroxysms.

Now in our cases the conditions were markedly different, as, firstly, the inoculations were carried out in almost all the cases during the day, and, secondly, the patients were restless and mentally active by night as well as by day. An analysis of 500 paroxysms was made and the following data are available for contrast:—

In the winter months 85·2 per cent. of the inoculations were carried out between 11 a.m. and 3 p.m., and 81·4 per cent. of the paroxysms occurred between 7 a.m. and 7 p.m; the maximum number of paroxysms occurred at 2 p.m.

In the months when the summer time was in force, 86·9 per cent. of the inoculations were performed between 11 a.m. and 3 p.m., and 74·7 per cent. of the paroxysms occurred between 7 a.m. and 7 p.m.; the maximum number of paroxysms occurred at 2 p.m. and 5 p.m.

A few inoculations were performed at midnight in the anticipation that by this measure most of the paroxysms would occur during the night or early morning. The alteration in the time of inoculation did not alter the times of onset of the rigors and so the practice was discontinued. The onset of the chills may show a definite time relationship to each other during the course of the fever. Very frequently one may see from the examination of charts from cases of tertiana simplex that the individual rigors tend to anticipate in time of appearance the previous rigor and so on, throughout the course, whereas in quotidian fever both anticipation and delay in the times of appearance may be encountered. Atypical charts were met with in three patients at their first inoculations. In each case an apyrexial interval (with diminished number of parasites present in the films) intervened between the early and late paroxysms, so that the charts read in this fashion:—

Case S. C.—Rigor (first), four apyrexial days, seven rigors (quotidian and tertian), thirteen apyrexial days, three tertian rigors and quinine.

Case P. S.—Nine tertian rigors, fifteen apyrexial days, three quotidian rigors and quinine.

Case W. L.—Five tertian rigors, five apyrexial days, seven quotidian rigors and quinine.

The question of the number of paroxysms that should be permitted in individual cases has always been of engrossing interest to us and of paramount importance to the patient. Our early cases were permitted to have as many as five to twenty-four paroxysms (chiefly from ten to twelve), but we soon came to the conclusion that a patient who was going to get better would do so after treatment with five rigors as with fifteen, and at the same time would be spared an unduly prolonged fever with its likely train of complications and sequelæ. Again, from a histopathological study of the brains of successfully treated cases of general paralysis of the insane, Straüssler and Koskinas [12] have found that at least five malarial crises are required before changes are initiated in the cerebral cortex to bring about a condition simulating the "stationary paralysis" of Alzheimer. Further, the reduction in the average number (from seven to eight) of rigors permitted has not been followed by a corresponding drop in the rates of recovery or improvement, so that our practice of allowing no fewer than five, but not more than ten, paroxysms of malaria has been apparently justified.

General paralytics and patients suffering from tabes dorsalis generally tolerate this form of fever extraordinarily well. In a small percentage of cases, prodromal phenomena in the nature of various sensory disturbances may make their appearance and herald the approach of a paroxysm. These subjective sensations occurred in tabetic and non-tabetic patients, and varied from a dull ache in the leg bones, especially the tibiæ, to the severe and lancinating pains in the joints or cramp-like pains in the calf muscles. Very often pains continued during the cold and hot stages of the paroxysm, and disappeared as soon as perspiration commenced. The physical signs that accompanied the recurring paroxysms of the fever were apparently similar to those observed in mosquito malaria, but mental reactions were naturally expected to occur more frequently in our patients and often did so in the later rigors. Delirious

states, hallucinations of sight and of hearing, paranoidal ideas and severe emotional outbursts with intense restlessness were encountered and, as often as not, exhibited a tendency to become more prominent in the hot and sweating stages of two or three paroxysms and then disappear. Several reactions in the nature of paralytic seizures complicated the picture in four cases. Herpes was quite common and appeared usually about the lips, less frequently about the nose, angle of the jaw, or malar bone. Attacks of gastro-enteritis with vomiting and diarrhœa were occasionally present, but they were never severe in type and always responded quickly to treatment. Sub-icteric staining of the skin and mucous membranes occurred in the final paroxysms of a few cases; the iodine and Gmelin tests of the urine were negative, but often the Russo reaction was positive; the blood-serum had a yellowish tinge and gave positive readings with the indirect reaction of the Van den Bergh test. Clinical jaundice with bile in the urine occurred in four cases at the thirteenth, thirty-first, thirty-second and thirty-ninth passages of the strain. The condition, which is always of serious significance and of grave prognostic import, appeared following the fifth, but nearly always after the seventh paroxysm. As a severe infection of the blood-stream with rapid and abundant hæmolysis of the red cells was suspected, the treatment was immediately brought to a close by the institution of quinine therapy. In three of the four cases the bile in the urine disappeared after three doses of quinine had been given, and at the end of a week no trace of bile staining of the tissues could be seen. The fourth case, which was also the thirteenth host, did not do so well and passed on to a fatal issue on the day after the jaundice appeared. In one instance, where the treatment was prematurely arrested because of this complication, a reinoculation was successfully performed at a later period, when the patient passed through a complete course of fever therapy without showing any signs of jaundice. Daily examinations of the urine revealed generally a darkly-coloured urine, acid in reaction and of increased specific gravity. Albuminuria was common, but usually no more than a trace was the rule; a marked increase occurred in two cases associated with pronounced constitutional reactions and indicated immediate stoppage of the treatment. Glycosuria (1 to 1·5 per cent.) was rare. The Russo reaction may be positive prior to the appearance of bile and was associated with sub-icteric staining of the tissues. Urobilinogen was slightly but infrequently increased. Hæmoglobinuria [9] fortunately did not occur. Enlargement of the spleen, as far as could be ascertained by palpation and percussion, was always slight even during the paroxysm; this was also confirmed in cases which came to necropsy. At the end of the fever there was usually a loss in weight, varying in individual cases from one to eight pounds, with an average of four pounds. Occasionally a gain in weight actually took place. Pallor of the skin and a mild degree of secondary anæmia were observed in most of the cases during the final paroxysms or at the end of the fever. As a general rule, the condition cleared up very quickly with the administration of quinine, and at the end of a week the blood-picture became normal. One of our cases, however, developed a profound anæmia with a dirty yellow tinging of the skin at the eighth paroxysm of a quotidian fever; the usual dosage of quinine was given, and although the parasites quickly disappeared the blood-picture did not appreciably alter, but closely simulated that often observed in pernicious anæmia. There was a marked reduction in the number of red cells (2,500,000), a leucopenia of 3,500 whites, a reduction of hæmoglobin to 20 per cent., numerous microcytes and megalocytes, normo- and megaloblasts (few), poikilocytosis, polychromasia and punctate basophilia. Arsenic, given orally and by the intravenous route, rapidly improved the condition and at the end of fifteen days the anæmia had completely disappeared. Deaths within a month of completion of the fever course occurred in eleven cases and formed 55 per cent. of the total number of deaths in adequately treated cases over a period of three and a half years.

The morphology of the parasite (*P. vivax*) was carefully studied in over ten thousand blood-films that were taken in all cases at every stage over a period of three and a half years; and we found that the parasite retained the form and characteristics of that seen in naturally infected cases and, despite the number of transmissions through the vertebrate host, crescents were never found. Schüffner's dots in infected red cells were common. The number of parasites varied enormously in individual cases and at the different stages of the paroxysm and fever. The most common form of the parasite to appear at the commencement of the fever was the trophozoite; later, schizonts and gametocytes were seen. The parasites showed a general tendency to multiply rapidly with the fever and to reach a maximum about the sixth or tenth day of the illness, when often a progressive diminution in numbers would set in and in some cases lead to the complete disappearance of parasites from the peripheral blood-stream. Cases in which spontaneous auto-immunization developed during the course of the fever presented these features and were frequently encountered. Multiple infections of the red cells were seen in several cases at different stages of the strain. The red cells usually contained more than one parasite and often as many as six or seven were counted; occasionally two gametocytes, two schizonts, or a gametocyte and schizont might be seen inhabiting the same red corpuscle. Pigmented leucocytes and white corpuscles containing parasites in all stages of degeneration have been found in the later paroxysms.

The susceptibility of induced malaria to treatment with quinine is remarkable. After a three-day course of treatment by the oral administration of hydrochloride of quinine—30 gr. on each of three consecutive days—the fever quickly subsides and the parasites rapidly disappear from the circulation. The quinine did not always prevent

the next succeeding paroxysm, but nearly always postponed the time of onset and diminished its severity. The parasites show an extraordinary diminution in numbers after the first dose of quinine and as a rule completely disappear by the end of the third day. It is this remarkable susceptibility of the parasite to quinine that renders control of the fever practically impossible. In a few cases the fever and parasites exhibited a tendency to disappear spontaneously and without treatment by quinine. Spontaneous auto-immunization of this nature took place in certain patients inoculated for the first time, and generally developed between the fifth and tenth paroxysms; the immunity, however, was not always complete, as frequently parasites increased in numbers and paroxysms reappeared within twenty-one days. Vagaries of this kind were, however, much more common in several of the seventeen cases which received a second course of treatment. The reinoculations were performed at periods varying in individual cases from twenty-two days to nineteen months after the primary injection; parasites were observed in the peripheral blood-stream of *all* the cases, and in 58·8 per cent. of the series several paroxysms of malaria occurred at regular and irregular intervals. Again, the fever and parasites spontaneously disappeared in nearly all the cases and the administration of quinine was rarely required. Our results at this stage are interesting, as Nicole and Steele have reported complete failures in the same undertaking with similar types of patients. It seems reasonable to suppose that an attack of induced malaria sets up an immunity process in the host which renders him partially or completely immune to a second infection—the maximum protection was required in our cases about the ninth or twelfth month after the first course of fever treatment.

Relapses in inoculated malaria are uncommon and accounted for two cases, or less than 2 per cent. of the patients infected with this strain during an observation period varying from two months to three and a half years. The first case, which has already been reported elsewhere [6], relapsed forty-two days after the last dose of quinine (total 90 gr.) and eighteen days following the fourth injection of novarsenobillon. The second patient relapsed twenty-eight days after parasites had disappeared following the administration of a short course of quinine (total 60 gr.). Both the cases were treated by the usual three-day course of quinine and no further relapses have been reported. The infrequency of relapses in this form of malaria emphasizes strongly the necessity of maintaining a strain of pure tertian for therapeutic purposes. Davidson [2] inoculated twenty cases of general paralysis of the insane with infected mosquitoes and reported thirteen (56·5 per cent.) relapses within an observation period of twelve months. Again, Yorke and Macfie [13], and later Yorke [14], reviewed a series of thirty-seven patients similarly infected, and reported twenty-one (57 per cent.) relapses in a period of observation varying from 291 to 609 days, and in the great majority of the twenty-one cases, relapses recurred after treatment. Evidently mosquito malaria is more resistant to quinine than the inoculated form.

We have been informed that many trypanosomes pathogenic to man and stock undergo a marked increase in virulence to certain species of laboratory animals when maintained in them for long periods by direct inoculation from one host to another. In some cases the alteration in virulence was attended by certain morphological changes which took place only after the strain had undergone a certain number of direct passages in the vertebrate host. It was therefore of considerable interest and importance to know whether the prolonged sojourn of *P. vivax* in man, comprising sixty direct passages during a period of three and a half years, had had any influence on the parasite, on the type of infection produced, or rendered it less effective in the treatment of general paralysis. A comparison of the infections comprising the first twenty passages with those of the last twenty passages has yielded data which indicate that the strain has undergone no change in pathogenicity or virulence or alteration in therapeutic properties during the direct passage from man to man through sixty generations. Again, the morphology of the parasite has not changed, and differs in no way from that found in naturally infected cases. Anopheline mosquitoes were successfully infected in the twelfth and fifteenth passages of the strain, but it is doubtful whether the parasite at this stage still retains the power to develop in the invertebrate intermediary host, as Gerstmann [3], in a recent publication, stresses the fact that after repeated passages from one human being to another the malarial parasite changes in such a way that it can no longer be infective to the mosquito, *Anopheles maculipennis*, or transmitted by them to man.

In conclusion, we should like again to acknowledge our indebtedness to Professors Stephens and Yorke, of Liverpool, for providing us with material to inoculate our early cases; to Dr. Clark, medical superintendent, for permission to publish these observations; and to Mr. A. H. Fann, senior laboratory assistant, for his kindly help and industry in the examinations of the blood.

STUDIES IN VACCINIA VARIOLÆ.

By MYER COPLANS, D.S.O., O.B.E., M.D.
From the Laboratory, Model Farm, Hendon.

PART I.

A RAPID process of rendering calf lymph bacteria free was described by me in the *Journal of Pathology and Bacteriology*, vol. xxv, 1922, p. 176. The process consists in adding to four parts (by weight) of a glycerine-phenol stock mixture of the following composition—

Glycerine, pure, neutral	...			50·0	parts,	by weight
Phenol ...	...	...	...	0·5	,,	,,
NaCl ...	...	...	...	0·8	,,	,,
Distilled water	...	...		50·0	,,	,,

one part of recently collected calf pulp taken at the 120th hour following vaccination. The mixture is finely ground and placed in an open beaker furnished with a glass stirring rod. To it there is added 1 per cent. of a stock solution of 1 per cent. Brilliant Green in distilled water and the emulsion is immediately stirred. The blue-green coloration rapidly disappears, but shortly returns on continued stirring within about ten minutes when allowed to stand exposed to the air. Thereupon the highly-coloured lymph is distributed into a number of sterilized cylindrical tubes each provided with a closely-fitting cork stopper, which is protected from contact with the lymph by the intervention of a layer of gutta-percha tissue. The tubes should not be completely filled with emulsion, a small air-space being left to facilitate shaking of the contents in the second and last stage of treatment. From time to time aerobic and anaerobic cultivation tests are carried out as to the presence of organisms, the former on agar slopes and the latter by deep stabs in one per cent. glucose agar. The tubes are incubated for not less than three days at 37° C., followed by seven days at 18° C., before a negative opinion as to the presence of contaminating bacteria is arrived at.

As a rule the emulsion becomes bacteria-free at the end of fourteen days' storage at room temperature (approximately 60° F.), the fineness of the emulsion accelerating the bactericidal action. Thereupon the highly bactericidal, somewhat viricidal, and almost venomously tissue-toxic dyestuff is converted into (in these respects) the comparatively inert leuco body by means of the addition of sodium hydrosulphite in *minimal quantity*, when the original natural colour of the lymph becomes restored.

The colour change is one of reduction, the reaction being the conversion of Brilliant Green into colourless Leuco Brilliant Green with formation of acid sodium sulphite. The proportion of sodium hydrosulphite necessary to bring about this change is from 0·25 to 0·5 grm. per 100 c.c. of the emulsion. The white powder is directly added to the emulsion in the tube, from which the stopper is but momentarily withdrawn. The stoppered tube should then be inverted and the contents rolled, shaken and mixed for several minutes, when commencing decolorization is noted. The well-corked tube of emulsion should then be set aside to stand for fifteen minutes, when complete decolorization of the contents will be observed and the emulsion is then ready for distribution into capillary tubes as desired. Before the reducing salt is added care should be taken to shake off all deposit adhering to the bottom and side of the tube so that the coloured contents are thoroughly mixed and evenly distributed.

To prepare calf lymph free from bacteria at the expiration of five days only, double the proportion of dyestuffs is added to the emulsion (i.e., 1 50000) reduction to the leuco body by the addition of the reducing salt being effected at the appointed time.

Great care must be exercised to avoid the addition of the reducing salt in excess of that actually required to produce decolorization within fifteen minutes. Experience shows that the decomposition products of excess of this material is capable of acting as a powerful vaccinicide, so destroying the potency of the virus.

The genesis of this rapid method of preparation of calf vaccine lymph arose in connection with the epidemic of virulent small-pox which commenced in Scotland in the early days of 1920. The sources of the outbreak appear to have included both India and Egypt. The following record, taken from the official sources[1], best indicates the circumstances:—

"On April 24 all local authorities were circularized, attention being drawn to the serious nature of the outbreak and the precautions that should be taken with a view to every authority being prepared for eventualities being indicated. The desirability of a widespread vaccination movement and the need for an adequate supply of calf lymph then engaged our attention. Arrangements were made with the Government Lymph Establishment (at *Hendon*) and (as the margin available for use in Scotland without unduly trenching on the English reserve supply soon proved insufficient to meet the needs of Scotland) with approved private firms for the supply of calf lymph sufficient for the needs of the whole of Scotland. . . The issues of lymph rose to 20,000 doses per day, and at times the maximum attained 30,000. . . . During the year, since the beginning of the outbreak, 845,711 nominal doses were distributed (*i.e., through official sources*). It was ascertained that the sales through wholesale houses and retailers attained unprecedented proportions."

(N.B.—*Italicised words added for explanation.*)

It should be noted that at this period the reserve supply of calf lymph of the English Ministry of

[1] Second Annual Report of the Scottish Board of Health, 1920, p. 52.

Health at Hendon amounted to a total of two million doses only, and as by the method employed in its preparation several months' storage is required to eliminate its original bacterial contamination before it can be considered as fit for use, the policy adopted of asking the Scottish Board of Health to make its own arrangements for the lymph supply appeared, in the circumstances, eminently wise.

At an interview at the Scottish Board of Health in May, 1920, the writer was informed of the situation, namely, that the English Ministry of Health was unable to furnish a total of more than 30,000 doses, i.e., less than three days' requirements, and was asked to undertake to arrange for the delivery of lymph during the month of June, at the rate of 10,000 doses daily. This was carried out, the lymph being prepared by the rapid process.

During the year 1920, the writer was responsible, without laboratory assistance of any description, for the preparation of over a million doses of lymph, a considerable proportion of which was utilized in Scotland in connection with the epidemic of small-pox.

The preparation of the lymph by this method is not only rapid, but simple, and its supply to meet epidemic crisis requirements does not necessarily involve the additional employment of specially trained personnel.

No untoward results have been experienced in the use of the specially prepared bacteria-free calf lymph for vaccination by means of skin scarification in man or the rabbit, or in the case of corneal scarification in the rabbit only. Immunizing experiments in man, involving subcutaneous injection of the lymph, or in the rabbit subcutaneous or intraperitoneal injections, show certain disadvantages attending its use. In man, persistent focal swellings are frequently seen at this site of injection within a few hours following inoculation, even when only one or two drops of the considerably diluted lymph are administered. In hypersensitive cases, an intense spreading swelling with œdema may result within a few hours, attended by considerable pain lasting from one to two days.

Similarly, in the case of the rabbit, focal nodules form at the site of subcutaneous injection; with repeated intraperitoneal inoculation, which appears to be attended by the production of a high degree of vaccinal immunity coupled with the presence of specific protective substances in considerable quantity in the blood, wasting of the animal at length occurs, and frequently, on post-mortem examination, there is found a condition of plastic peritonitis with adherent coils of intestine. The intravenous injection of calf lymph in rabbits is frequently attended by hæmorrhages, embolism and sudden death, even when finely comminuted and considerably diluted lymph has been employed. These immediate undesired effects would appear to be due rather to the presence of the alien (calf) epithelial and other tissue, hitherto inevitably associated with the vaccine virus in the lymph.

Opportunity has now been afforded for the observation over prolonged periods of the longevity as well as the potency of the vaccine virus present in calf lymph rendered bacteria-free in accordance with this rapid process.

A yield of 57 grm. of pulp obtained from a bull-calf (No. 2113) on August 30, 1921, the result of vaccination 120 hours earlier by seed lymph obtained from a calf vaccinated nine months previously (i.e., in December, 1920), was converted into vaccine lymph in accordance with the method. For a period of two and a half years this lymph was tested at regular intervals upon rabbits, both by the skin and eye reactions, with unvarying positive results. At the termination of this period the remainder of the lymph was employed for immunization purposes. Bull-calf No. 2074 yielded 25 grm. of pulp on October 20, 1920, following vaccination 120 hours earlier by calf seed lymph prepared in January, 1920. This pulp was likewise converted into bacteria-free lymph by the method described. It has now been similarly tested at regular three-monthly intervals upon rabbits for a period exceeding five years. In April, 1925 (i.e. four and a half years following the date of collection and preparation) its potency appeared to be undiminished. In July, 1925, the skin reaction alone proved positive, the primary eye inoculation for the first time proving negative: the remaining eye, however, yielded a typical reaction when reinoculated on the fourth day from the skin eruption. In October, 1925, a similar result was experienced with a fresh rabbit. Subsequently a bull-calf (No. 251) was inoculated upon the skin direct from the original calf lymph, and yielded a typical eruption by the 120th hour. Another bull-calf (No. 252) inoculated from the eruption on calf No. 251 likewise yielded a typical eruption. Thus the longevity of the virus has exceeded five years and a high degree of potency has been maintained during the first four and a half years of that period. During the first four years of storage the temperature at which this lymph has been maintained has varied from 7° C. to 12·8° C., and during the fifth year the temperature has been maintained at 5° C. approximately.

It is therefore proved that in these conditions of storage the virus suffers no particular injury by reason of the special treatment adopted for rapid process of preparation of bacteria-free lymph.

Candle-filtration of Calf-vaccine-lymph: Negative Result.

Attempts to effect separation of the virus from the tissue by means of the centrifuge have invariably failed, as have all attempts hitherto made by means of filtration through baked candle-filters. Whenever a watery or glycerine-water emulsion of vaccine-lymph is centrifuged, the virus appears invariably to be associated with the deposit of epithelial tissue: if the supernatant fluid be rendered free from visible suspended matter, it is invariably found to be virus-free also.

During the past fifteen years I have made a number of attempts to separate the virus from various tissue-emulsions by means of slow filtration

under varying degrees of negative pressure through candle-filters of various makes and constitution. Those who have worked with glycerine-water emulsions will know how difficult this material is to filter, even with little matter in suspension. In general two types of candle have been employed, viz., those into which either kieselguhr (infusorial earth) or kaolin largely enter. Those known in England as the Berkefeld and the Pasteur-Chamberland are representative of each type. Finely ground emulsions in glycerin-water and ether-saline, both of calf vaccine pulp and rabbit testicular virus (the latter kindly furnished me by Dr. H. Noguchi, of the Rockefeller Institute), have been employed with practically the whole range of Chamberland laboratory filter tubes, L1 (coarse) to L13 (fine) and "F" bougie (porosity=L5), also the German Berkefeld "V" type, English Berkefeld No. 25, and in addition a range of kieselguhr filters made by other manufacturers in England. In not a single instance has a filtrate been obtained in which the presence of the virus could be proved by ordinary inoculation tests upon the rabbit.

This circumstance is particularly noteworthy, especially when it is borne in mind that some of the Chamberland types of filter-candle employed in the tests readily permit the passage of organisms, viz., peripneumonia, tetanus spores and others as large as the *Bacillus diphtheriæ*, whilst the "V" type of Berkefeld filter will permit the passage of such small organisms as *B. pneumosintes* 0·15 to 0·3 micron in length.

The method employed by the Paris Laboratory for the French inspection (Contrôle) of the Chamberland filters (système Pasteur) previous to their sale appears to be sufficiently practical considering the enormous variation not only in the texture or porosity (due to variation in baking) of the individual candle, but as between individual candles of the same batch—all presumably of the same texture and rate of filtration. When comparison is made of, say, an L1 filter of a batch made at one date with another filter of similar nomenclature made at a later date, variations in colour may also be noted. The filters are made from pastes of mixed earths assembled from various districts of France, and different workmen may be employed on each occasion. Thus it comes about that an L1 filter-candle may show, under a constant pressure of five metres of water, a rate of filtration three times as great as that of an L1 filter of another batch; both pass the test as L1 filters and are marketed as such. They are identical in size and shape. In any case only one filter out of ten is subjected to the test before sale. An additional test to which all candles are submitted is the passage of air under pressure. The candle is placed under water and its interior connected by a flexible tube to a drum of compressed air maintained at a pressure of 1 atmosphere. An escaping stream of visible air-bubbles at any point from the outer surface of the candle ensures its immediate condemnation. It is the compressed air test to which a filter-candle used in a laboratory should be subjected prior to each new experiment before the validity of the subsequent test can be accepted. (I have often visited a filter-candle factory—unconnected with any of the foregoing—in which it was admitted that not a single test of any description had been applied to any of their candles before sale during the past thirty years).

The following experiments serve to illustrate the complete failure to obtain a virus-active filtrate from a finely-ground, comminuted and diluted calf-vaccine-lymph by means of a sound kieselguhr candle-filter, under negative pressure.

Protocol.—Calf lymph A.3 (50 per cent. glycerine) 50 c.c. taken and diluted with an equal volume of normal saline, and passed through Thomson's vaccine churn. 15 c.c. of the resulting emulsion set aside as No. 1 control. The remainder centrifuged in a Sharple's machine and 20 c.c. of the supernatant turbid fluid poured off and allowed to stand, when a deposit formed. The supernatant fluid (portion set aside as No. 2 control) thereupon passed through a German Berkefeld candle, "V" type.

First portion of filtrate after two hours' filtration = 1 c.c. clear: pale lemon-yellow tint (No. 3).
Second portion of filtrate after two hours' filtration = 3 c.c. faint trace lemon colour: clear (No. 4).
Third portion of filtrate after two hours' filtration = 3 c.c. faint trace yellow colour: clear (No. 5).

Five young rabbits selected and each inoculated on left cornea and dorsum (neck). One square inch of skin scarified, with materials No. 1 to 5 respectively. Rabbits subsequently kept in separate hutches.

Results.—Controls Nos. 1 and 2 each positive on eye and skin. Nos. 3, 4 and 5, entirely negative.

In another experiment British Berkefeld candle No. 25 was employed, its length being three inches and internal diameter half-inch. 50 c.c. of ground vaccine lymph was twice passed through a triturating machine as used in the previous experiment. This resulted in the production of an even emulsion which separated out slightly on standing twenty-four hours. The material was then centrifuged in a Sharple's machine for two minutes, and the turbid supernatant fluid was filtered under a negative pressure of twenty-five inches of mercury. In ninety-five minutes 50 c.c. of filtrate was obtained.

Samples of the material were collected at various stages and finally twenty-three young rabbits were each inoculated upon the eye and skin as follows:—

1. Control lymph, one rabbit.
2. First grinding, one rabbit.
3. Second grinding, two rabbits.
4. (*a*) Supernatant fluid from Sharple's centrifuge, three rabbits. (*b*) Deposit from centrifuge, one rabbit.
5. (*a*) Resulting slime left on outer surface of candle upon completion of filtration, two rabbits. (*b*) Filtrate, thirteen rabbits employed.

Result: Each of the ten rabbits tested under experiments 1-5 (*a*) proved positive, both for eye and skin. All the thirteen rabbits tested under 5 (*b*)

proved entirely negative. Thus whatever the type of candle-filter employed, whether kieselguhr or porcelain, all filtrates have been found to be entirely virus-free, and neither centrifuge nor filtration appears to offer any solution to the problem of the separation of the vaccine virus from epithelial or other tissue.

Separation of the Virus in quantity from Epithelial and other Tissues.

(*a*) *Increased Yield of Raw Vaccine Pulp.*

During the past five years, in order to obtain ample yields of raw vaccine pulp from vaccinated calves and to curtail the time and to facilitate the operation of inoculation involved in extensive scarification of the ventral surface of the calf (thorax excluded) and the inner aspect of each thigh, I have used an instrument similar in construction to the ordinary mechanical drawing-pen with the addition of a finger-plate so constructed as to provide a guard to limit both the depth and width of the two parallel incisions, namely, two millimetres in each case. The sketch of the instrument shown is drawn to full size (fig. 1).

This simple instrument enables the operator, without hesitation or danger, boldly to rule at one stroke regular double scarification lines in the desired direction on the animal's shaved skin, independent of—yet following—the movements (twitching, heaving) of the animal's body, which acts as the support for the instrument. An extensive area is thus scarified within a few minutes; there is no possibility of the danger of gashing, with bleeding, as frequently occurs when an ordinary scalpel is used for this purpose. By the use of this instrument, while the area of scarification is more extensive (as desired) the animal is considerably less exhausted, by reason of the speed of the operation. With large yields, the animal is killed and bled at the farm slaughter-house before the pulp is collected by means of a Volkman's spoon, subsequent to the necessary washing of the vaccinated area, and in this way admixture of the pulp with blood is avoided, as might occur with a living animal. The regular double scarification lines have the effect of producing a pulp which readily peels off in strips.

The following are the satisfactory yields obtained recently by my assistant (without previous experience) who undertook the entire responsibility of scarification, inoculation, and subsequent collection of the pulp from ten animals.

Eight bull-calves (age 3 to 5 months): 80·5, 55·5, 6·7, 97·2, 70·5, 53·97 and 46·5 grm., respectively.

One cow-calf (age six months): 50·5 grm.

One small kid (male) age three months, weight 0 lb.: 12·3 grm.

The average yield therefore per calf by this method is 66·37 grm. as contrasted with 31·6 grm., the average obtained from 103 calves vaccinated in 1920-21 with an ordinary scalpel.

N.B.—One gramme of pulp emulsified with 4 c.c. watery-glycerine usually yields a quantity of lymph sufficient for 500 human vaccination doses.

(*b*) *Separation of the Virus by Wick-Syphonage.*

This process for the freeing of the vaccine virus from epithelial and other tissue is the outcome of some earlier experimental work in connection with the purification of water in the field which was initiated by the writer at Leeds in 1913-1914 on behalf of the Army School of Sanitation, Aldershot. One particular phase of that problem was to clarify water expeditiously, whilst avoiding the use of a filter or chemicals, or mechanism containing moving

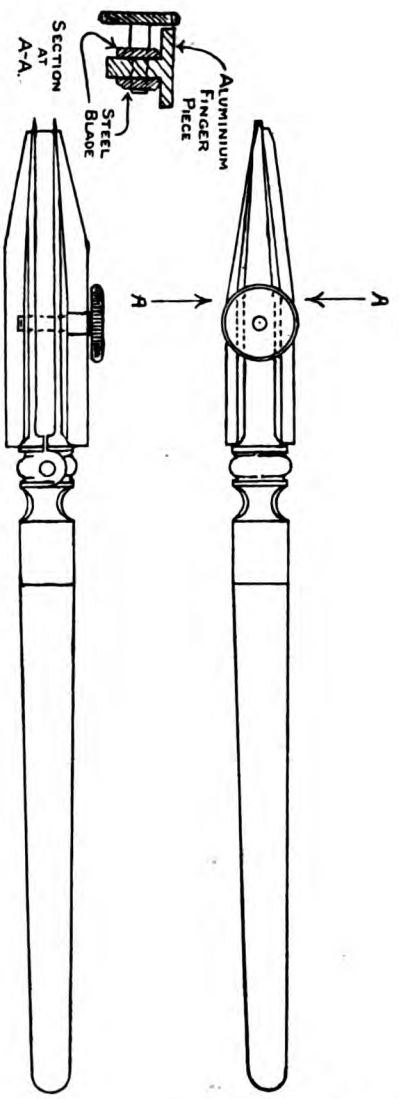

Fig. 1.—Double-bladed guarded scarifier. (Full size.)

parts. The principle of the method ultimately adopted by the writer, namely, wick-syphonage, has consistently yielded the desired results. It is based primarily upon the phenomenon, frequently observed, when a small pool of water is seen to be forming on the surface of the supporting table immediately underlying certain overhanging leaves contained in a bowl of flowers filled with water.

Overhanging moss (frequently), primrose, violet and many other leaves, may be culpable. Not all overhanging leaves give rise to the condition. Certain kinds of moss, when suitably placed, may be the means of the somewhat rapid discharge over the side of the bowl of the whole of the water contained in that vessel. It will usually be found that the water thus discharged is comparatively clear and free from plankton; it leaves little staining when the pool is removed. The physical phenomenon involved appears, in the first instance, to be one of simple capillary or surface attraction, the water rising and moistening one or both of the surfaces of the leaf which, if its free end overhangs the outside of the vessel to a level lower than that of the water contained within, thereupon commences to drip. Thus slow surface-syphonage is set up and maintained.

In the case of a mass of moss-fibres, surface capillarity means in effect the establishment of a number of minute continuous columns of water sheltered between the fibres, in addition to the simple moistening of the outer visible surface. If the whole mass overhang sufficiently, a double action occurs — central-syphonage and surface-syphonage—leading to frequent drip discharge of the contents of the vessel: this continues so long as the overhang reaches below the level of the water in the vessel. The "creeping" properties of mineral oils such as paraffin (kerosene) in wide and ever-spreading areas on certain surfaces, apparently irrespective of gravity, is a familiar phenomenon.

The whole of this phenomenon of surface-syphonage may be readily tested by means of filter-paper, or bibulous paper, cut into long, thin strips, each strip being supported by two long, fine wires threaded parallel through the paper to act as a support, and also to prevent collapse of the saturated paper when it is desired to make an artificial overhang. When a strip of paper hangs vertically so that its lower end is in contact with a liquid, the paper becomes moistened, the height to which the liquid rises depending upon the nature of the liquid. In a liquid placed in a watch-glass containing a mixture of several colloidal substances such as dyestuffs, it becomes possible at times to distinguish the several ingredients simply by the height to which the several components may rise. If it be a watery suspension, the watery component will often be found to rise to a height greater than that of any of the contained dyestuffs. If, when the maximal height has been attained to which the liquid will rise in the paper, the strip is bent over in the form of an overhang outside the watch-glass so that the extreme end of the moistened portion is depressed below the level of the liquid in the watch-glass, surface-syphonage is set up and the passage of the liquid onwards through the paper continues afresh. If the paper be torn off below the level of the liquid in the watch-glass, slow dripping takes place. If the experiment be carefully performed, it may be possible to separate the water from the colloidal matter, or even to separate colloidal substances from one another.

The action of filter-paper is not altogether mechanical, as is illustrated by the well-known experiment of placing a few drops of rosaniline hydrochloride upon a piece of flat filter-paper. The drop spreads, ultimately producing a clear, colourless peripheral zone which, on examination, is found to contain free hydrochloric acid; thus dissociation of the dyestuff has occurred. With surface-syphonage, therefore, it is not altogether a matter of the smallest sized particles or molecules in the fluid traversing the greatest distance; the nature of the wick or surface employed may exercise selective chemical or chemico-physical functions.

In the case of a wick similarly suspended and immersed, water rises throughout its substance, but, owing to imprisoned air, the rate of rise may be very slow. When the water has risen to a sufficient height in the wick to permit the adjustment of an overhang, dripping takes place from the free end. Columns of liquid have united within the fibres, and the action of flow and discharge from the free end of the wick is essentially the result of internal wick-syphonage. If, as a preliminary, the wick be plunged into boiling water, the contained air—a potential air-lock—is expelled and the wick immediately becomes thoroughly moistened. The wick may then be gently pressed to expel the excess of water. If the moistened wick be now arranged so that one end is immersed in liquid contained in a vessel, and the free end overhangs the outside of the vessel to a level below the level of the liquid contained within the vessel, wick-syphonage is immediately set up, and clear liquid shortly commences to discharge from the free end of the wick, the drip being maintained so long as the free end overhangs below the level of the water contained in the vessel. (This phenomenon is herein termed "wick-syphonage," in contradistinction to the ordinary rapid flow which takes place by syphonage through a closed tube.)

In connection with the experiments upon water purification, the crude water to be purified is poured into an ordinary vessel (No. 1) so as to reach a level within two inches of the upper margin, and an empty collecting bowl (No. 2) is placed at its side. A smaller graduated discarding vessel (No. 3) is also required, in order to receive the first portion of liquid to be collected and discarded when the volume passed over equals that originally retained in the moistened wick ("retention liquid"). A cleansed cotton or asbestos wick is selected, having a length *at least* twice the depth of vessel No. 1, and is made thoroughly wet by being plunged into boiling water. It may thereafter be suspended in the air, being held with forceps at one end in order to allow excess water to drip away from the lower or free end. The wick is then held by the middle, one half being submerged in the crude water, and the other half allowed to hang into the discarding vessel (No. 3). Shortly water free from turbidity slowly collects in the vessel until the graduated mark is reached, which indicates that the volume collected equals that originally imprisoned and retained by the wick after its withdrawal from boiling

water and the completion of the dripping of excess water, i.e., the original "retention liquid." The lower limb of the wick is then raised and transferred to the collecting bowl (No. 2), which slowly fills until at length the water stands in both vessels (Nos. 1 and 2) at the same level. If vessel No. 1 be raised, more water passes over. The rate of passage depends upon the size and looseness of texture of the wick, and also upon the number and material of the wicks employed. Wick-syphonage is always slower with an asbestos wick than with one made of cotton. All constrictions and sudden bends in the wick must be avoided, for these impede, and may arrest, the passage of the liquid. The wicks employed were cleansed by a preliminary immersion in ether, followed by a soaking in alcohol. Ultimately, when dried they were weighed, and again weighed after immersion in boiling water, followed by drainage of excess water. By this method the amount and volume of liquid finally retained or imprisoned in a wick of any particular length may be estimated. This is termed the "retention" figure, and the "discarding" vessel (No. 3) is graduated accordingly.

For uniformity in nomenclature, the following terms are employed in connection with wick-syphonage: The "wick-syphonate" is the liquid which is discharged from the lower end of the delivery or descending limb of the wick-syphon. The highest portion of the wick-syphon is the "summit"; the portion which lies between the summit and the floor of the vessel No. 1, containing the liquid to be purified, is the "collecting" or "ascending" limb; the "delivery" or "descending" limb is the portion which lies between the summit and the collecting vessel. The "submerged" portion of the wick is that which lies beneath the surface of the liquid to be purified; the "free" portion of the wick is that which lies outside this fluid. The "climb" is the vertical distance between the summit and the surface of the liquid to be purified in vessel No. 1. The "descent" or "fall" is the vertical distance between the summit of the wick and the surface of the liquid in the collecting vessel (No. 2). For experimental work, vessels Nos. 1 and 3 are so arranged that the lower or free end of the descending limb of the wick is at a level higher than that of the graduation mark for the latter. It is also advisable to arrange that the lower or free end of the delivery limb should terminate above the level of the liquid to be collected in vessel No. 2. In short, the end of the descending limb of the wick-syphon should always be free and terminate at a level above that of the fluid collected; it should not be allowed to dip into the syphonate.

Samples for examination to estimate the degree of purification may be collected at any moment from the dripping free end of the wick. In actual practice little adjustment is required if No. 1 vessel be tall and slender, and No. 2 be broad and low. A small hand-graduated beaker will serve as the "discarding" vessel No. 3 for collecting the first portion (retention fluid) of the syphonate to be rejected. The crude water to be selected for purification at Leeds was collected near the intake of the reservoir at Fewston. It is peaty in colour and contains asterionella, desmids, diatoms and siliceous particles, and is plentifully contaminated with bacteria. Slow passage through a single cotton wick yielded a clear, peaty-coloured fluid, in which all plankton and siliceous matter is absent; in general the bacterial content, as estimated by plating, was reduced by over 90 per cent., as compared with the raw water. With asbestos wicks, which permit only a very slow wick-syphonage, the syphonate is again clear, and contains less colouring matter; plankton and siliceous particles are absent, and the bacterial content is reduced by 97 per cent. As a rule, bacterial purification would seem to vary directly with the "climb," and inversely with the rate of flow. The submerged portion of a wick used for a considerable period will be found to become slime-coated, and even slime-choked, so impeding the rate of syphonage unless it be removed and cleansed. A simpler plan, however, is to change the wick. It was found that the slime-coating which appeared upon the surface of the submerged portion of the wick exercised a not unfavourable influence upon the quality of the syphonate; and in these respects, in so far as water purification is concerned, forms a very close parallel with the function exercised by the water-purifying slime-coat which forms in the superficial layers of a sand-filter-bed. The cotton wicks employed were 1 in. in diameter and $\frac{1}{8}$ in. thick, the weight being 21 grm. (approximately $\frac{3}{4}$ oz.) per yard. Two simple experiments show the capacity for purification of turbid fluids such as cow's milk, or china clay in watery emulsion, by means of wick-syphonage, the wicks employed being composed of asbestos (necessarily containing $2\frac{1}{2}$ per cent. cotton fibre in its substance as a supporting mesh), and pure cotton, respectively.

(1) *Kaolin emulsion in water.* — Exceedingly finely-ground and washed kaolin is shaken up with distilled water, in the proportion of 1 grm. per litre. After six hours standing, 200 c.c. of the supernatant turbid fluid is drawn off and set aside, and the remainder discarded.

(*a*) *Cotton-wick-syphon.*—100 c.c. passed through. Macroscopically: Syphonate appears clear, but, viewed through a depth of six inches, there is a faint opacity. Microscopically: Hanging-drop examination, no particles of kaolin seen.

(*b*) *Asbestos-wick-syphon.*—100 c.c. passed through. Macroscopically: Syphonate is bright and clear when viewed through a depth of six inches. Microscopically: Hanging-drop examination, no particles of kaolin seen. Syphonage action slow.

Thus, both asbestos and cotton wicks prevent the passage of particulate matter visible by direct microscopic examination; the asbestos wick prevented, in addition, the passage of particles of colloidal dimensions which cause the faint opacity.

(2) *Fresh cow's milk diluted* 1 *in* 10 *with normal*

saline.—This dilution is necessary to prevent choking of the wick by cream (fat) formation. 0·25 per cent. formalin added to prevent decomposition.

(*a*) *Cotton-wick-syphon*. — Macroscopically: Syphonate considerably clarified and somewhat opalescent. Microscopically: Syphonate contains only the smallest fat globules which are few in number. Fat globules of intermediate and large sizes, present in control, are entirely absent, as are all epithelial cells.

(*b*) *Asbestos-wick-syphon*. — Macroscopically: Syphonate shows a beautiful opalescence, and is semi-clear by transmitted light. Microscopically: Syphonate is free from all fat globules; epithelial cells entirely absent. Syphonage action is very slow.

The slime-coat which naturally forms on the upper layer of a water-purifying sand-filter exercises an essential function in arresting the passage of bacteria present in the traversing raw water. In the process of freeing the vaccine-virus from epithelial and other tissue by wick-syphonage (taking care always to avoid the use of asbestos-wick), a slime deposit always forms rapidly upon the upper and lower surfaces of the submerged portion of the wick, even when this passes obliquely through the lymph. Indeed, experience shows that a potent syphonate is more rapidly obtained when a very large surface of wick, thus plentifully slime-coated, is submerged, as occurs when the wick passes obliquely through the lymph in which it lies loosely coiled, without constrictions, free of the vessel wall, and resting on the bottom along its free edge only (i.e., preferably not flat). There is a distinct art in arranging the submerged portion of the wick to the best advantage. The slime-deposit, which consists of epithelial and other tissue containing the virus, is not intended to function as a bacteria-arrester. Indeed, the question of bacterial purification does not enter into the problem at all, for the lymph used in these experiments had all been previously rendered free from pathogenic organisms. It may be that the wick substance (cotton, worsted) by surface action dissociates the virus from the adherent slime-deposit, the liberated virus then being carried forward in the column of liquid slowly ascending the wick.

The sequence of events appears to be as follows: upon the setting up of wick-syphonage, there is a general draught of lymph from all directions towards the submerged wick and epithelial tissue rapidly deposits upon all exposed surfaces. The liquid slowly permeating through the slime epithelial deposit carries with it a considerable quantity of virus, and passing through the wick-syphon, is ultimately delivered into the collecting vessel. Here the liquid is seen to be free from epithelial tissue, clear or slightly opalescent, a small amount of colouring matter is present; vaccine virus is present in increasing concentration as the process continues. The first syphonate, consisting of the wick "retention fluid," must always be discarded. In the experiments for the freeing of the vaccine virus from calf lymph containing 50 per cent. glycerine, it was found that the establishment of maximal potency of the wick syphonate did not occur until after the wick had been functioning for one week, at least.

The apparatus adopted for prolonged wick syphonage (fig. 2) consists of a container or glass lipped beaker *A*, 2 in. in diameter, supported upon a special glass-holder *g*1, which rests on the floor of a crystallizing dish *B*, 3 in. in diameter which functions as the "collecting" vessel. *B* in turn is supported by a glass-holder, *g*2, resting upon the floor of beaker *C*, 4 to 4½ in. in diameter which acts as the "discarding" vessel. Beaker

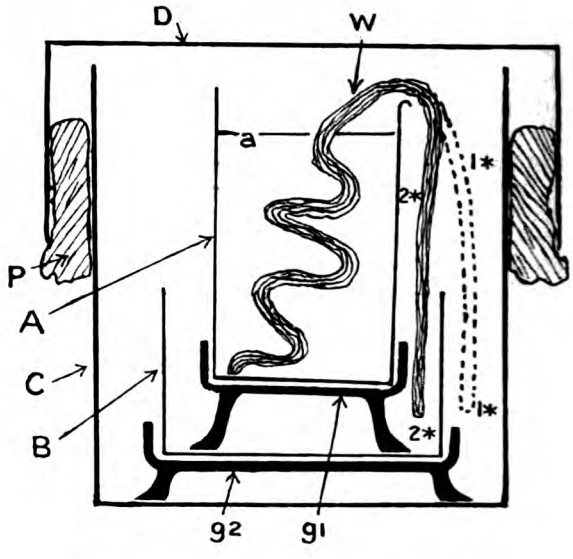

FIG. 2.—APPARATUS FOR WICK-SYPHONAGE.

A = vessel receiving lymph vaccine emulsion.
B = collecting vessel for wick-syphonate.
C = discarding vessel for wick retention-fluid.
D = cover. P = cotton-wool plug-collar. W = wick.
g^1, g^2 = quadruped glass supports for A and B, respectively.
W 1*—1* = position of wick delivering retention-fluid.
W 2*—2* = " " " " wick-syphonate.

C is capped by an inverted crystallizing dish *D* 5 in. in diameter. *P* is a circular string-fastened cotton-wool collar, which loosely plugs the interspace between *C* and *D*. The assembled apparatus is carefully sterilized, and when cooled 100 c.c. of the triturated vaccine, epithelial or tissue emulsion either in glycerine or saline-ether, is poured into *A* up to the level *a*, about 1½ in. below the level of the lip. A prepared 1-in. cotton wick, 7 to 8 ins. in length, the "retention figure" of which has been ascertained by previous trial, is then adjusted in the position W1*—1*, the lower free end of the descending limb terminating below the level of the floor of vessel *A*, and lying freely between the walls of *B* and *C*. Cover *D*, which in the meantime has been placed in an inverted position on a sterilized asbestos mat, is then lifted up and replaced in position over *C*.

Clear liquid shortly begins to drip from the lower free end of the wick and passes into discarding vessel *C*. The first portion to escape is that originally added to the wick in the process of moistening, and as soon as a quantity equal to the "retention figure" has accumulated in *C*, the liquid is again lifted, and the lower end of the wick is readjusted by means of sterile forceps, so as to occupy position W2*—2*, the terminal portion lying between *A* and *B*. Liquid now drips and passes into collecting vessel *B*, from which it is removed as required by means of a sterile pipette, the cover *D* being removed and replaced at each operation with the usual precautions.

During the process of wick-syphonage, the apparatus must be kept in a refrigerator at 5° C., although at this temperature the viscidity of the liquid is increased, and rate of syphonage is retarded. In the case of saline-ether emulsions (ether 10 per cent.), the apparatus, before transfer to the refrigerator, is placed in a slightly larger-sized receptacle, which can be readily rendered air-tight, in order to prevent subsequent evaporation and escape of the ether. (A tin-box with a well-fitting push-in lid is suitable for this purpose). It will be found that wick-syphonage, in the case of saline-ether emulsions, is somewhat rapid, but the syphonate yielded may be weak in virus-content in contrast with glycerinated syphonates, which, though slow in flow, are much more potent.

As soon as the liquid portion of the emulsion placed in *A* has been transferred by means of the wick to *B*, so leaving a soft slime or sediment upon the inside walls and floor of *A*, and upon all the previously submerged portions of the wick, a second extraction of virus from the slime residue may be carried out. For this purpose, the syphonate liquid in *B* is pipetted off, and the wick is carefully withdrawn with the aid of an assistant who, with two pairs of sterile forceps, holds the wick ends carefully apart. *A* is refilled (up to the level *a*) with a glycerine-water mixture (equal parts) or saline-ether (10 per cent. ether), in accordance with the previous constitution of the emulsion. With the aid of a glass rod—the end of which is flattened so as to function as a scraper—stirring then takes place, and the wick-syphon is carefully replaced in position W2*—2*. It is not necessary to remove the slime-deposit already formed upon the wick, and indeed this should not be done unless the wick has become slime-choked, and syphonage practically arrested. In this case, the slime-deposit should be scraped off the portion of the wick which has been submerged, and incorporated by being stirred with the contents of the emulsion in *A*, and a freshly-prepared wick is thereupon adjusted in position W1*—1*. The procedure thereafter is as already described with a primary wick-syphonage.

In order to ascertain the extent to which this extraction process may be profitably repeated, a quantity of glycerinated vaccine lymph (calf *A*1) was submitted to wick-syphonage for seven successive occasions, the experiment continuing over 203 days. The first four consecutive syphonates of the series gave typical reactions upon both sites, when 0·05 c.c. was inoculated upon the eyeball and shaved skin area at the nape of the neck of the rabbit. The fifth and sixth consecutive syphonates proved positive in the case of the skin only, the eye inoculations being entirely negative. With the seventh syphonate the reaction both to eye and skin inoculation proved negative.

At the termination of the experiment, portions of the pultaceous residue remaining on the wick in chamber *A* after the completion of the seventh extraction were inoculated both upon the eye and skin of a rabbit, with the result that the skin only proved positive, the eye being negative. This experiment was thereupon repeated upon a second rabbit, when the skin proved positive and the eye, after some delay, proved positive also. A portion of the untreated lymph set aside as a control was tested as to potency upon three occasions during the experiment, namely, at the beginning, in the middle, and again at the termination, and the results showed no appreciable loss of potency, either for eye or skin reactions. Incidentally, it may be noted that a portion of the first wick-syphonate inoculated upon the arm of an adult not vaccinated since infancy, gave typical vaccinia reactions, and six months later a calf inoculated upon the skin with the material also yielded typical vesicles by the fifth day following inoculation. Thus it will be seen that a considerable quantity of vaccine virus was obtained during the prolonged and repeated process of extraction of the epithelial tissue, although it has not been proved possible to liberate and abstract the whole of the virus content originally present.

To appreciate the significance of these results as bearing upon vaccinal potency, a "dilution-to-extinction" test was carried out upon a series of rabbits with potent wick-syphonate. For this purpose the left cornea of each animal was treated with 3 per cent. cocaine hydrochloride, and subsequently scarified and inoculated with 0·05 c.c. of the liquid; at the same time, an area of one square inch of the shaved nape of the neck of each animal was scarified and inoculated with a similar quantity. It should be noted that the area of the rabbit's cornea varies from 0·23 to 0·3 square inches.

The following are the results:—

		Rabbit number	Reaction: Cornea	Reaction: Skin
Control: undiluted wick-syphonate...		1	++++	++++
Diluted with 50 per cent. glycerine)	1 : 5	2	+++	+++
	1 : 25	3	+++	+++
	1 : 50	4	–	+++
	1 : 125	5	–	+++
	1 : 500	6	–	++
Diluted 1/1,000, 1/2,500, 1/5,000, 1/10,000 ...		7, 8, 9, 10	–	–

Thus a diminution of vaccinal potency is indicated by a delay in the onset of the typical eye-reaction, whilst the skin reaction remains typical. Further dilution leads to the abolition of the eye-reaction without impairment of the skin reaction. Still greater dilution leads to a limitation of the inten-

sity and extent of the skin reaction, and finally a stage arrives, with sufficient dilution, when both eye and skin reaction are entirely negative. The explanation may be that the actual immunity or resistance to the vaccine virus of the rabbit's corneal epithelium is greater than that of the skin, but the fact remains that the chances of a successful inoculation of the cornea may be diminished partly on account of the limited area involved, the area of the rabbit's cornea varying from 0·23 to 0·3 square inches, as compared with the area of inoculated skin (one square inch). Also there is the consideration that whereas by simple supervision the virus is allowed to dry upon the shaved skin at the nape of the neck (fortunately one of the few sites which is naturally beyond the reach of the animal's tongue), in the case of the eyeball not only is it impossible to attain drying of the virus contained in liquid vehicle, but much of the inoculation is laved off by the tear-secretion, coupled with the involuntary and constant movement of the eyelids over the corneal surface.

Whatever the explanation, it is a point of practical significance that progressive weakening of a vaccine virus in liquid vehicle is first indicated by a delay or disappearance in the corneal reaction of the rabbit, whilst the skin reaction remains apparently undiminished and unchanged.

By this method, progressive increase in the virus potency of a syphonate is likewise indicated. In the case of a viscid glycerinated calf lymph (*A*3) —a one-inch cotton-wick being employed, as before—the first 10 c.c. of colourless fluid was collected after forty-eight hours' syphonage, and was discarded as retention fluid; rabbit inoculations proved negative. The syphonate collected during the following six days was tinted, and repeated tests upon rabbits yielded typical skin-reactions, but in every instance the corneal reaction proved negative. Towards the termination of the first complete syphonage—six weeks later—when a total of 60 c.c. had passed over, liquid collected directly from the free end of the delivery limb of the syphon gave positive results upon both eyeball and skin of the rabbit. At this stage there was added to the residue of the lymph remaining in vessel *A*, a quantity of glycerine-water mixture, sufficient to make up the original volume, and the contents stirred, and the wick-syphon replaced. The subsequent syphonage, disregarding the first 10 c.c. passed over as representing the retention-fluid of the wick (although this retention-fluid was the residual undischarged portion of the first syphonate) immediately showed a maximal degree of virus potency.

With other glycerinated lymphs, the first 10 c.c. of the syphonate collected subsequent to the discharge of retention fluid has shown maximal potency within forty-eight hours. It will be noted that by using a single one-inch cotton-wick and filling the receiving vessel *A* with 100 c.c. of emulsion, a total of 25 c.c. may be syphoned over in ten days. During the first two or three days the daily rate of flow is 5 c.c., but subsequently the daily yield progressively diminishes, and towards the tenth day may be 1 or 2 c.c. only or even less. This is an indication that the wick is slime-choked and must be cleared of deposit or replaced by a fresh wick, if increased flow is desired. The composition of the glycerinated lymph used in these experiments is as follows: calf lymph pulp, 1 part; glycerine, 2½ parts; water, 1½ parts.

In the case of ether-saline emulsions, 1 part (by weight) of pulp is ground up with 3½ volumes of normal saline and ½ volume of ether is subsequently added. Wick-syphonage is comparatively rapid, the first 10 c.c. (colourless retention fluid) being delivered within two and a half hours. During the next twenty-four hours, a 30 c.c. tinted liquid was collected, and during the forty-eight-hour period following, 25 c.c. Thus the wick-syphon yielded a total of 55 c.c. in seventy-two hours. The potency of this rapidly syphoned material varies with individual pulps. In some cases the potency immediately attains the maximum of a potent glycerinated lymph syphonate, but more frequently it appears to be weaker, causing a typical eruption when inoculated in the rabbit on the skin only, the corneal surface remaining unaffected.

Variation in Wicks.

Increase of size and looseness of texture of the cotton-wick employed yielded a more rapid syphonate, and a similar result follows the employment simultaneously of a number of cotton-wicks. Plaited worsted wicks appear to function as efficiently as those made of cotton. Plaited silk wicks readily permit the passage of the virus by syphonage, but in the case of wicks made of asbestos fibre (containing 2½ per cent. cotton as a supporting substance) whilst slow syphonage is set up and a coloured fluid passes over resembling in appearance the syphonate delivered by a cotton-wick, upon inoculation tests being carried out with the rabbit the fluid is invariably found to be totally inert. Thus the asbestos material completely arrests the passage of vaccine virus in the syphonate.

(The exact composition of the fibre used in the manufacture of the asbestos wick employed in these experiments is apparently a trade secret. The wicks tested are those supplied to the writer at Leeds in 1913 by Messrs. Roberts, of Armley. Similar wicks are now manufactured from a mixture of short-fibre Canadian chrysotile-asbestos and Rhodesian asbestos the yarn containing from 2 to 10 per cent. cotton, as a basis.)

Protein as an Adjunct in the Treatment of Resistant Syphilis (Russell D. Herrold, M.D. *Journal of the American Medical Association*, February 6, 1926).—The injection of gonococcic protein intramuscularly in combination with neo-arsphenamin intravenously exerts a favourable influence on the reduction of the Wassermann reaction and on the clinical course, particularly the adenopathy. There is no deleterious action with the simultaneous use of the two methods of treatment.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—**All literary communications should be addressed to the Editors.**

4.—**All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.**

5.—**The Subscription, which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—**The Journal will be issued about the first and fifteenth of every month.**

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

VAGINAL THRUSH.

INFLAMMATORY lesions of mucous membranes caused by infection with various fungi are included under the term "thrush," and may be met with in various situations, being differentially designated by the name of the situation in which the lesion is found. Infection of the oral mucosa in this way has been the longest known and most frequently studied, so that when the term "thrush" is used without any qualifying adjective this is the condition usually understood. Of the remaining mucous membranes, that of the vagina is the one most frequently so affected, and to this condition the term "vaginal thrush" is often applied. Infection of the various mucous membranes with the thrush micro-organisms is very common throughout the tropics, but it may also be met with in temperate and even in cold climates.

It is generally stated that thrush is due to the fungus *Oidium albicans* Robin. Recent researches, however, both in the tropics and in temperate climates, have shown that the ætiology of thrush is far from being so simple as this, and that not one fungus only, but a number of different fungi may act as the causal organism. These different fungi may readily be differentiated one from each other by the application of appropriate biochemical methods. Thrush, therefore, whether of the mouth, or of the vagina, or any other mucous membrane, is not merely a single affection, but comprises a group of conditions clinically very similar, but due to different micro-organisms.

A critical study of the organism to which thrush is usually ascribed and which was originally described as *Oidium albicans* by Robin in 1853, shows that it really belongs to the genus *Monilia;* its correct name is, therefore, *Monilia albicans* Robin. That a number of different fungi have been included under this designation is evidenced by the different characters which have been ascribed to it by different investigators. Thus some have affirmed, whilst others have denied, that the organism liquifies gelatine, coagulates milk, and so on.

The genus *Monilia* comprises a group of the Fungi Imperfecti, and the Fungi Imperfecti possess the following characters. In the lesions the vegetative body (thallus) is composed of mycelial threads of rather large size, often showing arthrospores and numerous free oval or roundish, budding, yeast-like forms. In cultures, especially on solid media, mostly roundish or oval budding elements are seen, whilst mycelial filaments are scanty or may be absent. By subculture in various vegetable extract liquid media, however, the formation of mycelial filaments may often be restored. The monilias, as a rule, ferment sugars and other carbohydrates with the production of gas. This fact may be made use of in the identification of the different species of monilia, and also forms the basis of Castellani and Taylor's mycological method for the recognition of the different carbohydrates and other carbon compounds.

The more important monilias, which have been found in vaginal thrush in cases occurring in the tropics, in the Balkans, in Italy, and in England, belonged to groups *balcanica*, *pinoyi*, *metalondinensis* and *tropicalis*, and more extended investigation is considered likely to reveal other members of the genus in this condition.

A search of the literature shows that cases of vaginal thrush and of vaginal monilia infection have not been very frequently recorded, and the condition would not seem to be so well known as the condition warrants. In the typical vaginal thrush a membranous vaginitis is present in which thrush-like patches of membrane are present on the mucosa in which monilias may be observed both on microscopic and on cultural examination.

Other forms of vaginal moniliasis also exist, in one of which the inflammation of the mucosa is of the purulent type, no thrush-like membranous patches being present, but the secretion is thick and purulent, and in the absence of bacteriological examination the condition may be mistaken for gonorrhœa. Further, pruritus of the vagina, of the vulva and of the anus also occurs which is due to monilia infections.

Further, a similar symptomatology may also be induced by other members of the group of Fungi Imperfecti, and up to date there has been found in the vaginal secretion of native women suffering from vaginitis, fungi of the genera *Oidium*, *Aspergillus*, *Sporotrichum*, *Cladosporium*, *Sterigmatocystis*, *Cryptococcus*, *Willia*, *Vibriothrix* and *Hemispora*, and further investigation will probably reveal many more.

As all these fungi and the infections to which they give rise are more abundantly present in the tropics, and can only be established by bacteriological examination, it behoves the tropical practitioner to bear this condition in mind and to have the necessary bacteriological investigations carried out. Not only would he probably soon find fresh forms of causative fungi, but the recognition of their presence would also indicate the correct treatment to be employed, since the great majority of these fungus infections yield more readily to the topical application of iodine than to any form of medication.

Annotations.

The Relation of Albuminuria to Protein Requirement in Nephritis (J. P. Peters, and H. A. Bulger, *Archives of Internal Medicine*, February, 1926).—A study of the nitrogen metabolism of certain patients with acute and chronic parenchymatous nephritis has been made in an attempt to determine to what extent protein lost as albumin in the urine can be replaced by food protein. The total urinary nitrogen of these patients is not a satisfactory measure of nitrogen catabolism. The nitrogen catabolism can only be estimated from the urinary non-protein nitrogen after proper allowance has been made for changes in blood and tissue nonprotein nitrogen and variations of body weight due to diuresis or accumulation of œdema. By the administration of large amounts of carbohydrate and fat it has proved possible to reduce the protein catabolism to from 0·5 to 0·7 grm. per kg. per day. If enough protein is given to cover the nitrogen catabolism plus an additional amount equivalent to that lost as albumin in the urine nitrogen wastage may be prevented. Most of the patients when they enter the hospital show evidences of previous protein deficiency. If they are given more than enough protein to replace the amount lost in the urine they will store the excess within certain limits thus repairing the effects of previous nitrogen wastage. This protein wastage may be partly due to early dietary mismanagement. The loss of protein as albumin in the urine is certainly a serious contributory cause. It also seems probable that the disease itself, in its acute stages at least, is characterized by a higher protein metabolism than normal. Abnormally high blood-protein nitrogen has only been observed when the nitrogen catabolism was relatively high and has usually returned to the normal level as the clinical condition of the patient improved and the nitrogen catabolism diminished.

On the Occurrence of Paralysis after Treatment with Antirabic Vaccine (J. W. Cornwall and W. A. Beer, *Indian Journal of Medical Research*, January, 1926).—These studies show that fresh normal nerve substance is toxic to both rabbit and men when injected subcutaneously. The toxic dose varies widely with the individual, some showing paralysis after less than 20 mg. per kg. of body weight, others tolerating over 1 grm. per kg. without inconvenience. The action of phenol renders the nerve substance slightly less toxic. In antirabic treatment it is desirable to be able to increase the dose of the antigen. This could be done by separating the antigen from its toxic vehicle or by neutralizing the toxicity of the vehicle; the latter seems the more practicable alternative.

Pneumococcic and Streptococcic Peritonitis: Report of Twenty-three Cases in Infancy and Childhood (B. Lipshutz and H. Lowenburg, *Journal of the American Medical Association*, January 9, 1926).—Pneumococcic and streptococcic peritonitis is a comparatively frequent abdominal lesion in infancy and early childhood. The majority of these cases occurred in children under two years of age. Fifty per cent. were preceded by a definite pharyngeal infection or coryza, the latter antedating the onset of the abdominal symptom by from four to seven days. The clinical picture is characteristic. Differentiation of the streptococcic from the pneumococcic type can be made only by means of smears or a culture of the exudate. The peritonitis always begins as a pelvic peritonitis. An early operation is recommended to prevent any error in diagnosis and to give an outlet for the peritoneal exudate. All supplementary measures directed toward overcoming the profound sepsis that sooner or later dominates the clinical picture, have been without avail.

STUDIES IN VACCINIA VARIOLÆ.

By Myer Coplans, D.S.O., O.B.E., M.D.
From the Laboratory, Model Farm, Hendon.

(*Continued from p.* 130.)

Part II.

(1) Properties of the Liberated Vaccine Virus.

(A) *Centrifuging.*—A series of saline-ether and glycerinated syphonates has been subjected to prolonged centrifuging in order to obtain some evidence as to the physical configuration of the virus. 4-in. glass tubes were selected and each filled to a depth of 3 in. with selected syphonate. The tubes were carried in buckets which swing at a radius of 6 in. The speed of the centrifuge was variously estimated at 1,500 to 2,000 (nominal 2,000) revolutions per minute, and centrifuging was carried out at maximal speed continuously for four hours. Subsequently, corresponding with each centrifuged syphonate, three rabbits were inoculated on eyeball and skin as follows: (*a*) Control, not centrifuged. (*b*) Supernatant fluid: 0·05 c.c. taken from uppermost layer of centrifuged liquid in tube. (*c*) 0·05 c.c. taken from lowermost layer.

There was a general agreement as to the results, save that the onset of the symptoms in the case of centrifuged material derived from the supernatant layers was in every instance slightly delayed as compared with the control.

Assuming this correspondence of results to be within the limits of variation in reactions experienced amongst rabbits when a series is inoculated with the same virus, it may be stated that the virus-content of the liquid is but very slightly diminished as the result of centrifugal force. No grounds have been afforded by this experiment for speculation as to the physical condition of the virus.

(B) *Filtration.*—The entirely negative results obtained by filtration of glycerinated calf lymph through porcelain and kieselguhr filter-candles have already been referred to. An additional series of filtration tests under negative pressure with potent saline-ether and glycerinated wick-syphonates has been carried out with Chamberland filter-candles of type "L2" and the German Berkefeld "V." The former permits the passage of large organisms, and the latter, the *Bacillus pneumosintes*. In the case of saline-ether emulsions, 5 c.c. passed through both "L 2" and "V" filters in a few seconds. In the case of glycerinated syphonates, with a negative pressure of 28 in. of mercury, filtration took place at the rate of 1 c.c. per hour in the case of the porcelain filter, and at the rate of ½ c.c. per hour with the kieselguhr filter. In each and every instance the filtrate proved entirely negative when inoculated upon the eyeball and skin of a series of rabbits. The liberated virus appears to be incapable of passing a sound filter which has been found to permit the passage of organisms as large as the *Bacillus diphtheriæ*. It should be noted in this connection that the "L2" filter was employed in these experiments only after a preliminary trial had shown that it was impossible to employ an "L1" filter for the filtration of glycerine-syphonates, the glycerinated liquid failing altogether to pass this filter even after prolonged negative pressure lasting one hour.

(C) *Experiments with Mineral Earths and Wood Charcoal* [4].—It is obvious from the foregoing experiments that the non-passage of the virus through the candle-filters must be due to other than simple mechanical causes. In order to investigate the matter further, fresh unused "L2" and "V" candle-filters were obtained and pulverized in an "end-runner" mill, mechanically driven at 100 revolutions per minute for half an hour. The fine powders were then added severally in varying proportion to glycerinated and saline ether wick-syphonates, of known potency, placed in stoppered tubes. The tubes were hand-shaken for a few minutes and set aside in the refrigerator to deposit for several days, the shaking being repeated at intervals. At the end of this period, the tubes were gently centrifuged and a series of rabbits were inoculated with the deposits and supernatant fluids respectively.

A fresh rabbit was used for each examination, a particular deposit being inoculated upon the eye and the neck of the same rabbit, this animal being used for no other experiment: similarly with a supernatant fluid.

The results are as follows:—

I. Added: 10 per cent. "V" Berkefeld Candle-Filter (kieselguhr) pulverized.

(1) *Wick-Syphonate from Glycerinated Lymph* (*Calf A* 4).

(*a*) Supernatant fluid: Rabbit No. 81. Eye and skin both negative.

(*b*) Deposit: Rabbit No. 82. Eye and skin both negative.

(2) *Wick-Syphonate from Saline-ether Lymph* (*Calf* 251).

(*a*) Supernatant fluid: Rabbit No. 77. Eye and skin both negative.

(*b*) Deposit: Rabbit No. 78. Eye and skin both negative.

II. Added: 33 per cent. L2 Chamberland Candle-Filter (porcelain) pulverized.

(1) *Wick-Syphonate from Glycerinated Lymph* (*Calf A* 4).

(*a*) Supernatant fluid: Rabbit No. 90. Eye negative, skin ++.

(*b*) Deposit: Rabbit No. 89. Eye ++++, skin ++++.

(Result (b) confirmed with rabbits 91, 91B, 91C and 110B).

(2) *Wick-Syphonate Saline-ether Lymph* (*Calf* 251).

(*a*) Supernatant fluid: Rabbit No. 92. Eye and skin negative.

(*b*) Deposit: Rabbit No. 91. Eye ++++, skin ++++.

III. The following are control tests on the untreated wick-syphonate.

(1) *Undiluted Wick-Syphonate Saline-ether Lymph* (*Calf* 251).

Tested on eye and skin of rabbits Nos. 58, 71, 75, 103B and 104B: Skin ++++, eye negative.

(2) *Wick-Syphonate from Glycerinated Lymph* (*Calf A* 4).

Tested on eye and skin of rabbits Nos. 1B–10B:

Undiluted	Skin ++++	Eye ++++
Dilution 1/5, 1/25	,, +++	,, +++
,, 1/50, 1/125 ...	,, +++	,, negative
,, 1/500	,, ++	,, ,,
,, 1/1,000, 1/2,500	,, negative	,, ,,
,, 1/5,000, 1/10,000		

The several activities of the powders obtained from the pulverized "L2" and "V" filters were further investigated, and inasmuch as these filters are composed, respectively, largely of kaolin and kieselguhr which have been subjected to fierce furnace heat (calcination) for prolonged periods, each syphonate has been treated with raw kaolin and also with kaolin which had been subjected to heat in an open porcelain dish over a Bunsen flame in the laboratory (i.e., partly calcined kaolin, not vitrefied): similarly with raw kieselguhr and with this material likewise heated for a short period in the laboratory (i.e., partly calcined kieselguhr).

The results are as follows: In the case of raw kieselguhr added to the two syphonates there is no appreciable effect: the supernatant liquid appears to be unaltered as to potency. The deposit shows no evidence of having become activated by the virus. In short, raw kieselguhr functions as an inert substance in the presence of vaccine virus. In the case of partly calcined (laboratory-heated) kieselguhr, the result of admixture with the two syphonates is closely comparable with that obtained by the pulverized Chamberland "L2" candle-filter. The virus is found to be completely removed from the saline-ether wick-syphonate when the supernatant fluid is tested both on the eye and skin of rabbits, and the activity of the deposit is likewise correspondingly increased, so that it now yields complete reactions both on the eye and skin of the inoculated animals, whereas the untreated syphonate, whilst affecting the skin, does not affect the inoculated eye of a rabbit. Similarly with glycerinated syphonate, which contains a very high virus-content, there is also marked diminution in potency of the supernatant fluid, coupled with corresponding increase of virus (vaccinal) activity of the deposit.

The action of the pulverized Berkefeld "V" (kieselguhr) candle-filter upon the virus contained in both potent wick-syphonates derived from the glycerinated lymph A4 and the saline-ether lymph 251, *is to render the liquid completely inert: the deposited powder is also completely inactive.*

The action of the pulverized Chamberland "L2" *(porcelain) candle-filter* upon the two potent wick-syphonates *is*, in the case of the glycerinated syphonate, *to remove over 98 per cent. of the virus from the liquid, the deposit being exceedingly active*: in the case of the saline-ether syphonate, the liquid is rendered completely inactive while the deposit is found to be of an increased potency, and affects not only the skin, but also the eye of the rabbit. Thus the powder possesses two separate functions: it causes the disappearance of the virus from the liquid, and at the same time the deposited powder has gained a virulence corresponding with the quantity of virus which has disappeared from the liquid. *The "L2" candle-filter has become sensitized by the virus removed from the filtering liquid. The action of the kieselguhr candle-filter is to render the virus in the filtering liquid entirely inert.*

Raw kieselguhr powder therefore appears to be without effect upon the virus; partially calcined kieselguhr powder (laboratory-heated) removes the virus from the liquid and the deposit becomes correspondingly sensitized; completely calcined kieselguhr powder (furnace-heated) causes the liquid to become completely inert, the deposit being also completely inert. To use a chemico-physical expression, the raw kieselguhr is inert, partially calcined kieselguhr adsorbs the virus and becomes correspondingly active. The explanation of the action of the calcined kieselguhr may be similar, in that the virus is also adsorbed from the liquid, but is so completely bound to the surface of the particles of the powder as to prove inert when inoculated upon the eye and skin of a sensitive animal such as the rabbit.

From these experiments two means are indicated not only for removing the vaccine from the wick-syphonate, but also of concentrating the virus in higher potency upon the surface of the powders employed, namely (1) the material obtained by pulverizing the "L2" Chamberland filter, and (2) partly calcined kieselguhr.

Raw and partially calcined (laboratory-heated) kaolin—the latter not being allowed to vitrefy—acting upon the potent glycerinated wick-syphonate, are severally found to resemble that of the pulverized Chamberland "L2" porcelain filter-candle. The supernatant fluid is entirely inactive, whilst the deposit is correspondingly exceedingly active. These deposits, after removal of the supernatant fluid, have been found to retain their potency for over six months. (Still under observation.) The virus activated deposits obtained from the glycerinated wick-syphonate have been subjected to further treatment by (*a*) repeated washing with normal saline followed by centrifugation, or (*b*) 50 per cent. water-glycerine mixture, likewise followed by centrifugation. This process has in each case been consecutively repeated for six occasions, so that any supernatant fluid originally moistening the particles of the deposit has been diluted to over one millionth part of the original amount. The result of this process has been that, in each case there has been no loss of virus activity exhibited by the deposit when inoculated upon rabbits in accordance with the normal procedure. No question, therefore, arises that the supernatant fluid may possibly harbour any accessory factor necessary for the virus to exercise full activity. The whole of the virus appears to be attached to the surface of the particles of raw kaolin, and the method of washing is an additional process for purifying the deposit from contaminating matter.

The action of asbestos powder upon the potent glycerinated wick-syphonate is comparable with that of kaolin, the supernatant fluid becoming inert and the deposit correspondingly active, the activity persisting for several months.

It has already been shown (above) that the wick-syphonate passed by an asbestos wick is complete inert as to vaccinal potency.

Meerschaum powder, both raw and partially

calcined, has been similarly tested, the results resembling those obtained with kaolin.

Wood charcoal ("Norit" brand, obtained from brazilnut shell) has also been similarly tested. There is, at times, a difficulty in sedimenting this material, especially when mixed with glycerinated wick-syphonate, and in such cases centrifuging does not materially help deposition. There is considerably less difficulty with the saline-ether wick-syphonate, and the supernatant fluid, when completely free of particles of charcoal, is found to be inactive, whereas the sediment is correspondingly active.

Thus a variety of materials present themselves for removing the vaccine virus from the wick-syphonate, namely, wood charcoal, certain raw mineral earths, and some of the latter baked or ired (calcined) in varying degree.

From these experiments, means are clearly indicated not only of removing the vaccine virus from a weakly potent wick-syphonate, but also of concentrating the virus in higher potency upon the surface of the powders specially employed, and in this connection the material obtained by pulverizing the Chamberland L2 filter and also partially calcined (laboratory-baked) kiesulguhr powder have proved particularly successful.

(D.) *Immunization Experiments upon the Rabbit.*—(1) *Intravenous Inoculation.* To each of a series of fourteen young rabbits there was administered intravenously, viâ the ear marginal vein, wick-syphonates obtained from glycerinated calf lymph (A4), in the proportion of 2 c.c. per kilo body weight, the syphonate having been diluted before administration with normal saline in the proportion of one part of syphonate to four parts of saline. Only one dose was administered to each rabbit. At the same time, areas of the external surface of both ears, nape of the neck, shoulders, haunch, and abdomen, were shaved. On the fourth or fifth day following, a fine, papular rash developed more or less profusely on both surfaces of each ear, and reached the maximum on the ninth or tenth day, when the papules, having increased in size, became umbilicated. In some cases umbilication was earlier. From the eleventh to the thirteenth day, the papules became dry and peeled off in the scabs. About the fourth or fifth day, occasional discrete papules of larger size, about two to three millimetres in diameter, each surrounded by a zone of erythema, developed upon the shaved area of the skin of the neck, shoulder, or haunch. No papules were observed upon the abdominal surface. The papules upon the body, shortly after their appearance, also became rapidly vesicular, umbilicated, then pustular, and becoming dried, the scabs separated from the ninth to the twelfth day. The body eruption was typical in appearance, and, as confirmation, rabbits inoculated upon the neck and eye with material derived from the vesicles developed typical lesions. Material from these lesions was passed by inoculation through a series of three animals, whereupon each in turn developed typical vaccinal lesions, both upon the eye and skin.

Observations upon the rectal temperature of all the animals which received the intravenous dose showed, with two exceptions, that upon the fourth and fifth day there was a rise of temperature of from 1° to 4° F., which fell within the following two or three days to normal limits. With the two exceptions there was no rise of temperature.

(2) *Intraperitoneal Inoculation.*—Two additional animals each received intraperitoneal injections of diluted wick-syphonate, the dose administered being similar to that employed for the intravenous tests. No rash or rise of temperature was subsequently observed in either case.

During the period of thirty-one days, at varying intervals from the twelfth day onwards, all the animals treated intravenously or intraperitoneally were once inoculated upon the eye and skin with potent glycerinated calf lymph. In no instance was a positive skin reaction observed. Both the animals treated intraperitoneally developed eye lesions only, whilst three out of the fourteen rabbits treated intravenously developed eye lesions only, the skin reaction proving entirely negative in the fourteen animals.

Thus it is shown that whilst the whole of the treated animals proved refractory to inoculation by skin scarification upon the body, five of the animals were sensitive to the infection by means of inoculation upon the scarified cornea.

The fourteen animals of the series subjected to preliminary vaccination by intravenous inoculation were at various intervals (up to the 213th day) subsequently revaccinated with potent calf lymph, and in some instances the revaccination has been four times repeated. With every revaccination, both eye and skin were inoculated save in one instance in which the skin reaction only was tested. (This exception was on the 181st day on the occasion of the fourth revaccination of rabbit No. 19B, when, as before, the skin reaction proved negative.)

The second revaccination of ten surviving animals which proved to be negative to both eye and skin reactions at the first revaccination, took place at intervals varying from 40 to 120 days after the intravenous inoculation. Two rabbits proved positive to both eye and skin, five were positive to the eye only; three animals proved entirely negative.

The third revaccination of the three animals found negative at the second vaccination took place at intervals of 100 to 171 days following the intravenous injection; all three again proved entirely negative.

The fourth revaccination of these three animals took place at an interval of 174-213 days. Two of these revaccinated for the fourth occasion upon the 174th and 180th day, respectively, proved entirely negative. The third proved on the 213th day to be positive to the eye only, the skin reaction proving entirely negative. This animal had previously been vaccinated for the third time on the 171st day, with entirely negative results.

Control tests with the selected calf lymph were

repeated during this period upon normal rabbits, both upon the eye and skin, and in all the cases the resulting reactions were typically positive.

For the purpose of comparison as to the degree of immunity developed as the result of primary inoculation (vaccination) by means of scarification of the skin and cornea, a series of eight young rabbits was inoculated each upon the eye and skin with potent glycerinated calf lymph, with the result that typical lesions developed both upon the eye and skin in each animal. Thereupon, during the period of thirty days following, at varying intervals from the twelfth day onwards, the eight animals were reinoculated with the same calf lymph upon the skin and upon the cornea of the eye previously unvaccinated. The results were as follows: In four of the animals, typical lesions developed upon both the eye and skin; in three animals the reaction was positive in the case of the eye only, the skin proving negative. One animal only of the series proved entirely refractory both to the skin and eye inoculation. It will be seen that, upon revaccination of these animals, in no case did the skin reaction prove positive whilst at the same time the eye reaction remained negative.

Comparison is therefore afforded for testing the degree of immunity produced in rabbits by the intravenous method of inoculation by means of wick-syphonate with that obtained by the process of skin and eye scarification with calf lymph; the superiority of the former method during the period under review is striking. It should be noted that throughout these immunity tests the use of lymph derived from virus obtained from rabbits has been strictly avoided; only calf vaccine lymph has been employed. In the process of revaccination it has also been usual to avoid revaccinating an area of skin which has been inoculated in previous tests, and in addition the eyeball revaccinated has been the fellow to that inoculated upon the previous occasion. In no instance in these tests has an eyeball which yielded a positive result upon a previous occasion been revaccinated; such tests are invalidated inasmuch as it is known that with the eyeball, as with the skin, a local reaction may give rise to an immunity strictly localized to the reacting area.

Table I affords facilities for making a ready comparison of the several immunities established by the superficial, intravenous, and intraperitoneal methods of primary inoculation (vaccination).

It will be seen that of a total of fifty-two revaccinations carried out upon twenty-four rabbits, upon twenty-six occasions the eye and skin reactions were both negative; on six occasions only were the skin and eye reactions both positive; on nineteen occasions the eye reaction alone was positive, the skin reaction proving negative. *Upon no occasion was the eye reaction negative when the skin reaction proved positive.* Thus if the eye reactions be disregarded and attention be paid to the skin reactions only—vide columns (5), (6) and (8)—upon six occasions only would these animals have been found positive, whilst upon the remaining forty-six occasions they would have been deemed negative.

Table II illustrates the severity of the eye an skin symptoms observed upon revaccination animals in which the primary inoculation (vac cination) was performed by means of vaccinat of the eye and skin of each animal with glycerinate calf lymph.

Table III applies similarly to those animals which the primary inoculation (vaccination) w performed by the method of intraperitoneal intravenous injection of the wick-syphonate obtain from glycerinated calf lymph.

Tables II and III (upon which Table I is base shew that in not a single instance did the eye r action remain negative when the skin reacti proved positive, whilst in six animals in which bo the eye and skin reactions had proved negati upon previous tests, the first onset of returni sensitiveness was manifested by the positive reacti of the eyeball only.

Reference has already been made above to t necessity of employing a lymph of sufficient va cinal potency in order to produce a typical reacti on the rabbit's eyeball, yet in the case of t rabbit's skin the same lymph, diluted many time continues to produce typical reactions, althou the diluted material proves innocuous when inoc lated upon the eye. The explanation may be o of higher natural immunity of the corneal epith lium as compared with the skin, or it may be d to mechanical difficulties of obtaining a satisfacto inoculation.

Therefore, if in the case of an animal in which co plete protection both to the skin and eye reactio has become established by immunization, there a return of sensitiveness manifested by the *eye reaction alone*, it is obvious that the insusceptibil to vaccination by skin scarification alone is criterion of the susceptibility of the animal gen rally to the action of the virus when the path infection takes place otherwise than by the ski

If it be a fact that the eyeball is normally mo resistent than the skin to artificial infection- in any case it is more difficult to vaccina the eyeball—it follows that the returni sensitiveness of the eye to vaccination wh the general vaccinal protection is passing off whil the skin still remains insensitive is positive evidenc of supersensitiveness of the eyeball, and possibl of the body generally, towards infection by t virus.

(2) *Production of Immune Sera.*—(A) *Calves.* T sera of those animals from which large yields vaccine pulp were obtained (previously referred t have been tested as to their capacity to prote rabbits against vaccination by the skin and e by means of potent calf lymph

Calf A1. Red ♂, aged six months, yielde 80·5 grm. of vaccine pulp at 120th hour. Sla tered thirteenth day. Yield 1,300 c.c. seru (0·4 per cent. ether added).

(*a*) *Neutralizing tests in vitro*: 1 vol. of ser was added, respectively to 4, 2, 1 and ½ vols glycerinated calf lymph of full potency, and t several mixtures were warmed at 37° C. for h

ADDENDUM.—(*Not referred to in text, nor included in Table I.*) Fifth revaccination. Interval: 366 days.

Rabbit No. 11. Eye + + + + (intense reaction), skin + + (crusts separated on ninth day).
,, ,, 12. Eye + + + (severe reaction), skin + (crusts separated on seventh day).

an hour. With each mixture, a rabbit was inoculated upon the eye and skin, and all four rabbits proved entirely negative.

(*b*) *Tests in vivo*: Six rabbits were each given serum subcutaneously or intraperitoneally, the quantity varying from 1 to 15 c.c. per kilo. At the same time each animal was vaccinated upon the eye and skin with calf lymph.

Results as follows:—

Rabbit No.	Dose per kilo c.c.	Eye	Skin
Control test 1	0	++++	++++
,, ,, 2	1	++++	++++
,, ,, 3	2½	++++	+++
,, ,, 4	5	+++	+++
,, ,, 5	7½	+++	–
,, ,, 6	10	+++	–
,, ,, 7	15	+++	–

A further quantity of serum was treated by one-third saturation with ammonium sulphate and the precipitated euglobin redissolved in normal saline was made up to the original volume of serum. Three rabbits were treated similarly to rabbits Nos. (5) (6) and (7) above, each receiving as a protective dose 7½, 10, and 15 c.c. per kilo body weight, respectively. Upon vaccination, the lesions produced resembled those of rabbits Nos. (5), (6) and (7).

Calf A3. Yield: 55·5 grm. vaccine pulp. Animal slaughtered fourteenth day. Three rabbits given respectively 5, 10, and 15 c.c. serum per kilo body weight, and each vaccinated at the same time. Both eye and skin lesions developed in all three cases. The skin lesions in the rabbit receiving the largest protective dose were slight.

Calf A4. Yield 46·7 grm. vaccine pulp. Slaughtered fourteenth day. Rabbit given 15 c.c. serum per kilo body weight and vaccinated. Result: eye lesion fully developed; skin lesion negative.

Calf B2. Yield 49 grm. vaccine pulp. Serum obtained twenty-second day. Rabbit tested as for Calf A4, with similar result. Serum obtained forty-ninth day: no protective effect—thus resembling serum of unvaccinated calf.

Calf B1. 97·2 grm. vaccine pulp. Slaughtered fourteenth day. Three rabbits treated with 5, 10, and 15 c.c. serum respectively, per kilo body weight. Result: protective dose: 5 c.c., eye + + + skin negative. Protective dose 10 c.c. and 15 c.c., eye +, skin reaction doubtful. Serum was administered to a rabbit (15 c.c. per kilo body weight) twenty-four hours before vaccination, with the result that the eye reaction was considerably delayed and proved only slight, the skin reaction being entirely negative. Serum administered in large quantities up to a period of twenty-four hours subsequent to vaccination appeared only to delay the onset of the eye symptoms, which ultimately proved typical, as were those of the skin.

Serum administered to rabbits after twenty-four hours following vaccination appeared to be without protective effect. (N.B.—Serum from calves A3, A4, B2 and B1 given subcutaneously.)

Four full-grown rabbits fed daily for four days in succession with 20 c.c. of serum were each inoculated upon the second day. In three animals typical lesions developed unchecked, both upon the eye and skin; the fourth animal proved completely refractory.

These experiments show that a certain degree of protection against vaccinia is capable of being exercised in rabbits by the administration of serum drawn from calves which have been the subject of an extensive skin eruption; the quantity of serum necessary seems, however, too great for practical purposes.

(B) *Goats* Nos. 1 and 2.—Serum collected on the 5th and 42nd days, respectively, subsequent to extensive scarification, showed no protective action against vaccinia when administered subcutaneously to rabbits in doses of 15 c.c. per kilo body weight.

(C) *Rabbits*.—A series of rabbits has been treated by repeated intraperitoneal injections of potent bacteria-free calf-lymph, the total amount of lymph administered in each case varying from 5 c.c. to 25 c.c.; the period over which the immunizing inoculations were spread varied from fourteen days to three months. The rabbit serum upon examination *in vitro* was found to be capable of neutralizing in each case four times its own volume of potent calf lymph, when the mixture was warmed at 37° C. for half an hour. The rabbit serum, upon subcutaneous administration to rabbits, was proved to have a far higher protective value against subsequent vaccination with calf lymph than the serum obtained from extensively scarified calves. In so far as the eye reaction is concerned, this was prevented by the administration of immune rabbit serum, 1 c.c. per kilo body weight only being given, but in these cases the skin reaction proved positive.

It would almost appear necessary, if it be desired to abolish both eye and skin reactions in the rabbit to administer the mixed sera of immunized calves and rabbits.

It is interesting to note that when a mixture of heated immune rabbit serum mixed with an equal volume of calf lymph and warmed at 37° C. for half an hour was tested upon the eye and skin of a rabbit, delayed eye symptoms occurred, the skin reaction proving negative. This experiment was repeated with a mixture of two volumes of lymph to one volume of serum, when both eye and skin reactions were completely negative. The test was again performed, using four volumes of lymph with one volume of serum, with the result that skin lesions developed, the eye proving negative. (The temperature of the heated serum had been raised to 50° C. for one hour, on three successive days.)

On repeating the three experiments with the same serum unheated, all three animals proved entirely negative to both skin and eye reactions. The phenomenon noted in which the eye reaction proved positive only in the presence of a mixture of vaccine virus and excess of neutralizing immune serum approximates to that already described by Neisser-Wechsberg [5] with other neutralizing mixtures in which the immune serum appears to be in excess.

SUMMARY.

(1) Calf vaccine lymph rendered bacteria-free ithin a few days by the Leuco-Brilliant Green rocess has been found to retain its potency for veral years. This method is specially applicable the rapid purification of lymph to meet epidemic quirements.

(2) An instrument designed for the purpose of pid and extensive vaccination of calves is described. This consists of a double-bladed scarifier ith a finger-plate so adjusted as to provide a ard to limit the depth and width of the two rallel incisions.

(3) A method is described for the liberation of ccine virus from epithelial tissue by means of ick-syphonage. Rabbits inoculated intravenously ith the liberated virus develop generalized vaccinia. he liberated virus is proved to be a non-filter sser. The action of filter-candles in completely esting the passage of the virus has been investigated, and also the behaviour of the virus in e presence of certain mineral earths and wood harcoal.

(4) The phenomenon seen in previously immunized rabbits of returning sensitiveness of the orneal epithelium to vaccine inoculation whilst e skin remains refractory is described and discussed. Does it indicate a negative phase in the abbit and the waning of protection against variola this animal?

(5) Experimental results are stated as to the otection afforded to rabbits against vaccinia by eatment with sera obtained from immunized alves, goats and rabbits.

Acknowledgment is made of the services of my ssistant, Miss E. G. Wilkinson, in connection with his research during the past two years.

Morphologic Variations in a Ringworm Species n the Toes (Fred. D. Weidman, M.D., *Archives f Dermatology and Syphilology*, March, 1926).—ollowing the implantation of a non-pathogenic east directly on a ringworm lesion of the toes, a ingworm species, the primary culture of which had ad a constant morphology for three years, suddenly hanged from the downy to the powdery type. his variability means that we just expand our conception of the extent to which variation may occur n identical ringworm species as they come directly rom the lesions and make due allowance therefore n the determination of species. This applies particularly to members of the *Trichophyton gypseum* roup.

Abstract.

ON THE CARBON TETRACHLORIDE TREATMENT OF ANKYLOSTOMIASIS, WITH A NOTE ON THE HOOKWORMS OF PENANG.[1]

By A. NEAVE KINGSBURY, M.B., B.S.(Lond.), D.P.H., D.T.M. & H.

Pathologist, Institute for Medical Research, F.M.S.

WHILE on a tour of inspection, in 1923, Dr. A. L. Hoops, Principal Civil Medical Officer, Straits Settlements, requested the writer to undertake the treatment of a series of ankylostomiasis cases with carbon tetrachloride. Oleum chenopodii had been extensively employed in the District Hospital, Penang, by Dr. J. C. Tull, and as the carbon tetrachloride series would be carried out in the same hospital, and under similar conditions, it was thought that the investigations should yield valuable information regarding the comparative efficiency and toxicity of these drugs. So much has, however, been published on the efficiency of carbon tetrachloride during the past two years, that it is not intended to stress that part of the investigation, but rather to record the toxic manifestations noted, and to examine the biometrics of the hookworms of Penang.

In 1923, the pharmacology of carbon tetrachloride had not been thoroughly investigated. From its close chemical relationship to chloroform it appeared that fatty infiltration of the organs would probably result from its exhibition, and extensive fatty change in the liver had been recorded in a few human and canine cases. This condition already exists when there is advanced anæmia, and it was, therefore, decided only to include in the series cases with hæmoglobin exceeding 30 per cent.

On admission to hospital, the stools of all patients were examined by the film method, and the hookworm cases were passed to a special ward for treatment whenever no other serious disease existed. Treatment included a saline purge at night, followed by 2·5 c.c. of carbon tetrachloride on the following morning. One hour later this dose was repeated, and after an interval of two hours a second saline purge was administered. The worms were collected by washing and sent in formol saline to the laboratory, where they were counted and identified. Pressure on the hospital beds unfortunately precluded routine repeat treatment, and the flotation method was employed for determining any residual infection, seven days after the exhibition of the anthelmintic. The series comprised 155 cases. Of these, twelve absconded or were discharged at their own request before observation was completed.

INTENSITY OF INFESTATION AND HÆMOGLOBIN.

In Table I the cases are grouped according to the intensity of infestation, and the average percentage

[1] Abstracted from the *Trans. of the Roy. Soc. of Trop. Med. and Hygiene*, January 21, 1926.

TABLE I.—SHOWING THE INTENSITY OF INFESTATION AND HÆMOGLOBIN.

Number o hookworms	Less than 25	26 to 50	51 to 100	101 to 150	151 to 200	201 to 250
Number of cases (total 138) ...	101	21	9	2	2	3
Percentage of cases	73·3	15·2	6·5	1·4	1·4	2·2
Average percentage of hæmoglobin ...	61	59	55	55	30	42
Theoretical loss of hæmoglobin caused by hookworm infection ...	2	6	11	19	27	35
Average percentage of hæmoglobin plus theoretical loss through hookworm infection	63	65	66	74	57	77

of hæmoglobin is included for each group. In the *Report of the Commission for the Relief and Control of Hookworm Disease in Australia and Dependencies*, it is claimed that, on the average, a reduction of 10 per cent. in hæmoglobin is caused by 65 hookworms. Based on this factor a *theoretical* loss of hæmoglobin due to the average number of hookworms has been introduced into Table I, but the resultant figures indicate that no such simple relationship exists in the present series. Mhaskar (1924) was also unable to establish any definite connection between the intensity of infection and the fall in hæmoglobin. It appears, rather, that the human host is largely capable of compensating for the anæmia-producing factor until the number of hookworms approaches 150, but with more massive infections a rapid fall in hæmoglobin occurs. Many of the coolies were, however, also suffering from chronic malaria, and the average physical condition reflected the then existing economic situation, which was the sequel of the post-war rubber slump.

About 5,000 patients are admitted annually to the District Hospital, and of these some 12 per cent. were found to harbour hookworms. Three-quarters of the cases in the present series were infected with less than twenty-five worms, so that in not more than 3 per cent. of admissions was this intensity of infection exceeded. Only 0·6 per cent. were found to harbour more than 100 hookworms. A portion of the cases came from the town area, in which the pail system for night-soil collection is in vogue, but the majority were from outlying villages and coconut and rubber plantations. Areas of high infection do exist, particularly in some of the kampongs (villages) and on a few estates, but if only 3 per cent. of a typical population show a higher infection than 25 worms it must be conceded that the disease is not a serious one in the locality, and that the situation compares favourably with that in other tropical areas.

THE EFFICIENCY OF CARBON TETRACHLORIDE.

The criterion for discharge was a negative flotation test for ova, seven days after treatment. In five of 138 cases ova were demonstrated after treatment, and in one case two worms were found at autopsy. It may be suggested that the oviparous powers of the female worms were adversely affected by the anthelmintic, thus accounting for the high percentage of " cures " obtained, but Sweet (1924) has shown that any such effect of carbon tetrachloride has passed by the seventh day. It is not claimed, however, that the drug caused the expulsion of all hookworms in the remaining 133 cases. Soper (1924) found that, after a negative flotation test, repeat treatment is frequently followed by the expulsion of a number of worms, but the percentage of " cures " (96) is comparable with the percentage (84) obtained by Tull (1923) with oleum chenopodii.

Particulars of the hookworms from the five cases which were positive after treatment are embodied in Table II. The percentage expelled following the first treatment was 84, and the figures confirm the observations of others that *Necator americanus* is more easily dislodged than *Ankylostoma duodenale*.

TABLE II.—FAILURES WITH CARBON TETRACHLORIDE.

he results from this small number of cases also ıggest that the male necator may be more resistant treatment by carbon tetrachloride than the male, and the female ankylostome than the male.

Post-mortem Findings.

Five of the 143 cases died in hospital at intervals ter treatment of 44 days (amœbic dysentery); 25 ıys (pulmonary tuberculosis); 26 days (chronic terstitial nephritis); 24 days (bacillary dysentery); ıd three days (carcinoma). An assumption should ɔt be hastily arrived at that carbon tetrachloride prone to cause an acute exacerbation of the chronic ysenteric condition which is frequently seen in the siatic coolie. There is no doubt that the drug ıuses some intestinal irritation, but only in two of 43 cases did dysenteric symptoms supervene, and ı both there was an interval of three days between reatment and the appearance of any quantity of ıucus in the stools.

The first, second, third and fifth cases came to utopsy, and, although the numbers of hookworms xpelled after treatment had been 176, 19, 28 and 0 respectively, worms were found in the fifth only, he number being four. Macroscopic examination ınd histological sections of liver and kidney in the irst, second and third revealed no lesion referable o the anthelmintic. The fifth was a case of carcinoma in an elderly Tamil patient. The condition was not diagnosed ante-mortem, for no abdominal tumour was palpable and the liver was unenlarged. At the autopsy, however, the liver substance was found extensively invaded by carcinomatous deposits. Histologically the growth was found to be secondary to an intestinal cancer, although a prolonged search at the post-mortem examination had failed to localize the primary growth. The histological picture of the liver included a generalized fatty infiltration. Around secondary deposits in the liver a zone of fatty change is frequently seen, but in this instance the infiltration appeared to involve the whole hepatic parenchyma. The change is thought to be due to the action of the carbon tetrachloride, though no necrosis of liver cells was seen, and sections of the kidney showed some interstitial fibrosis but no change attributable to the drug.

The Toxic Manifestations of Carbon Tetrachloride.

The drug was subjected to chemical tests for impurities before administration was permitted. About 30 per cent. of the cases complained of such symptoms as nausea and vomiting, thirst, or a burning sensation in the epigastric region. Some 20 per cent. experienced giddiness, and in a few instances a transient nephritis, evidenced by hyaline casts, occurred. In one case a temporary albuminuria developed.

Since the completion of the above series, the writer has observed marked toxic symptoms in three additional cases, particulars of which are given below:—

Case 1.—A European, aged 52, with no clinical evidence of hepatic insufficiency, and a reliable non-alcoholic history, was given 4 c.c. of carbon tetrachloride followed by a saline purge. The bowels acted vigorously on the following day, the patient became slightly jaundiced, the icterus deepening during the three succeeding days. Diarrhœa was profuse, and the motions contained a quantity of mucus. The stools were examined on three occasions, but were negative for *Entamœba histolytica* and the dysentery group of bacilli. The patient became so weak that he was unable to walk to and from his bed, and the condition of the heart gave rise to anxiety. The urine contained bile; and albumin, which had been absent before treatment, appeared in quantity. Convalescence was very prolonged and normal vigour was not regained for upwards of two months. With the lead acetate, sodium hydroxide, and alcohol test recommended by Dr. Andrew Balfour, a definite darkening occurred with this specimen of carbon tetrachloride. A sample was returned to the manufacturers, who reported that, although a trace of carbon disulphide was present, the quantity was within the recommended limits.

Case 2.—A Malay woman, aged 35, was given 3 c.c. of carbon tetrachloride followed by a saline purge. Three days later the writer was again asked to see her. She had had nausea and intermittent vomiting since taking the drug. Giddiness and deafness were also complained of, and the sclerotics were slightly yellow. There had been no movement of the bowels for four days. Following a brisk purge many hookworms and ascaris were expelled, after which the symptoms rapidly subsided. The batch of carbon tetrachloride was found to be pure, and the symptoms were doubtless caused by the absorption of the drug in some quantity from the alimentary canal.

Case 3.—The inclusion of this case is due to the courtesy of Dr. J. G. Reed, who has investigated the value of confined carbon tetrachloride and oleum chenopodii in mixed hookworm and ascaris infections. He submitted to the writer material obtained at an autopsy, and also supplied the clinical notes of the case. The patient was a Tamil child, aged two years, who was admitted to hospital with signs of a massive infection. Hookworm and ascaris ova were present in large numbers, and the urine contained a trace of albumin. She was given ol. chenopodii 2 minims, and a number of round hookworms were expelled. Six days later carbon tetrachloride, 10 minims; ol. chenopodii, 4 minims; and ol. ricini 100 minims were given. The following day the œdema of feet was less marked, but weakness increased and death occurred thirty-six hours after the taking of the mixture. Histologically the liver showed massive fatty infiltration and some round-cell infiltration, but no central necrosis. Such fatty change is not infrequently seen in the livers of young children, and a few small areas of cellular infiltration are not uncommon in the tropics. The kidney showed extensive pathological changes. The glome-

rular epithelium was swollen and the capillary tufts dilated. The tubules contained a number of casts, and degenerative changes were present in the tubal epithelium. Collections of small round cells occurred throughout the organ. Albumin had been present in the urine before treatment, but the glomerular changes were probably due to the anthelmintic. This specimen of carbon tetrachloride was found to be pure.

Like all vermifuges, carbon tetrachloride is not without danger to the host, and its administration is frequently followed by sequelæ of a toxic nature. Such symptoms are rarely serious, and are to some extent paralleled by the sequelæ of oleum chenopodii, which is a less effective and more expensive anthelmintic in ankylostomiasis. In the opinion of the writer, carbon tetrachloride for medicinal use should be absolutely pure, and, even then, is contra-indicated in case of marked anæmia, alcoholism, hepatic insufficiency, chronic bowel diseases, and advanced renal cases, though Leach, Haughwout and Ash (1923) have found that it could be exhibited without anxiety to patients with a mild degree of renal disturbance. Case No. 2 indicates the necessity for bowel action within a short time of taking the drug, and patients should be instructed to report if no movement occurs within twelve hours. Under certain conditions the administration of carbon tetrachloride is fraught with danger, and it should not be prescribed until a careful clinical examination has been made.

Hookworm Biometrics in Penang.

The hookworm fauna of Malaya has been investigated in Fort Swettenham, Kuala Lumpur, and Singapore by Darling, Barber and Hacker (1920). New arrivals from China were then found to harbour 33·8 per cent. of ankylostomes and 66·2 per cent. of necators. In another group of Chinese, some of whom had been resident in the country for twenty years, the ankylostomes had increased to 38·4 per cent. Incoming Indians had 97·1 per cent. of necators and only 2·9 per cent. of ankylostomes. After residence in the country the latter percentage increased to 5·1. In the Federated Malay States there is little intermingling between Chinese and Indians, and hence each race tends to keep its own hookworm index, but Penang has a large fixed population and more mixing of the races occurs.

The cases of the present series are grouped in Table III, according to nationality and length of residence. The ratio of *A. duodenale to N. americanus* is found to be much higher in Indians of short local residence than would be expected. The tabulated results also show a marked increase in the ankylostome/necator ratio with length of residence for both Chinese and Tamils, and after ten years in Penang the hookworm indices of the two races approximate.

Chinese and Northern Indians are known to have a high ankylostome/necator ratio, but in Tamils the proportion of ankylostomes is usually low. In Penang 65 per cent. of the population is Chinese, and of these some 38 per cent. are born locally. It thus appears that immigrants to Penang gradually acquire the high ankylostome index which is characteristic of the Chinese.

The sex ratio (males to females) for *A. duodenale* was 1 : 1·61 and 1 : 1·54 in Tamils and Chinese respectively, and 1 : 1·23 and 1 : 1·17 respectively for *N. americanus*. *A. ceylanicum* was obtained from one patient, a Tamil who had resided for 25 years in Penang, and who also harboured *N. americanus*.

TABLE III.

Nationality	Length of residence in Malaya	Number of cases	*Ankylostoma duodenale* Group Total	*Ankylostoma duodenale* Ratio M/F	*Necator americanus* Group Total	*Necator americanus* Ratio M/F	Ratio *A. duodenale*/ *N. americanus*	Total hookworms for group	Average hookworms per case
Indians	Less than 5 years	42	431	1:1·6	905	1:1·2	1:2·1	1,336	31·8
	5 to 10 years	14	222	1:1·5	343	1:1·3	1:1·55	565	40·4

Current Literature.

Annales de la Societe Belge de Medicine Tropicale.

June, 1925.

Investigations on Alastrim in the Belgian Congo (L. Van Hoof).—Alastrim has been considered by some authors to be indistinguishable from small-pox or varicella. These investigations have shown it to be quite a distinct disease. The author has come into contact with the three infections at Stanley Pool for many years, and clinical facts differentiate them one from the other. Jennerian vaccination was of no value in the last epidemic of alastrim at Stanley Pool; on the other hand cow-pox is frequently inoculable to people cured of alastrim. Cow-pox does not immunize the monkey against the inoculation of alastrim, and alastrim does not immunize the monkey against the inoculation of the vaccine. The allergic virus taken from the monkey causes in man early

actions which are less intense than those of the imal, and are not followed by phenomena of neralization. The prophylactic measures against astrim are isolation, disinfection, and although nnerian vaccine has not always proved efficaous, it should not be abandoned. The clinical gns are not generally sufficient for the diagnosis alastrim and small-pox, and the two affections ay exist simultaneously, and the vaccination ould consist of a mixture of vaccine and specific mph against alastrim.

A Case of Asymmetrical Juxta-articular Nodosity a European in the Belgian Congo (R. Bernard d A. Broden).—The patient, a married man, ed 32, had been in the tropics for nine years, ring which time he was quite healthy, with very w attacks of malaria. Nothing to be noted in s family history. The infection began at the ginning of his fifth year in the Belgian Congo d continued for nearly five years before he prented himself for treatment in 1923. The case clearly not of syphilitic origin, it is possibly a se of yaws, but the diagnosis is very indefinite.

Stovarsol or "Acido Acetylxylaminophenylarsinic" the Treatment of Human Trypanosomiasis (F. an den Branden).—This product, which has been ported by many authors to have such a good fect in the treatment of syphilis, has not proved s efficacy in the treatment of yaws and human ypanosomiasis in the Congo. Natives can take rge doses for several consecutive days, but ovarsol has only a slow and short trypanocidal ction.

A Case of Intestinal Bilharziasis due to Schistoma hæmatobium (L. Dupuy).—Intestinal bilarziasis is very frequently met with in Katanga. t is often found in association with some other arasitic or intestinal infection. Of nineteen cases xamined, eighteen were of *Schistosomum mansoni* nd only one of *S. hæmatobium*, which is the first ported in Katanga. The patient was suffering om amœbic dysentery, which was cured in five ays by injections of emetine. On the sixth day umerous eggs of *S. hæmatobium* were found in e stools. The usual treatment was administered nd the patient cured.

Contribution to the Clinical Study and Treatment f Yaws (L. Dupuy).—Yaws is a common disease etween North and North-East Rhodesia, especially the villages near the River Luapula and its tribuaries. It is known under the name "Bonono." uring the author's three years' stay in these parts 55 natives presented themselves for treatment. he clinical aspect of yaws is described in detail. he secondary lesions are very variable, and are asily diagnosed. Tertiary lesions, however, lead o errors of diagnosis and are often confounded ith syphilis. Tertiary arthritis is a mono-articular anifestation of a clinical type and quite different rom tertiary sclerosis of yaws; it is soon cured f treated in the early stage. Large doses of N.A.B. should be used, the minimum being 04 eg. per kilo of weight. In tertiary lesions novarsenical and iodine treatment should be prescribed.

The Treatment of Animal Trypanosomiasis with "205 Bayer" (R. Van Saceghem).—These experiments have not given such good results as were expected. The sterilization of the peripheric circulation brought about by the injections was of very short duration. Large doses, 15 grm. to 100 kilos weight, prove fatal for bovidæ; at autopsy lesions of the liver, intestine and kidney are found, and the blood is not coagulated. "205 Bayer" is more active against *Trypanosoma congolense* than against *T. vivax*. This product is very much inferior to emetin.

Annotations.

The Rate of Loss of Hookworms in the Absence of Re-infections (A. C. Chandler, *Indian Journal of Medical Research*, January, 1926).—The following is the summary given by the author: Opinions differ widely as to the rapidity with which hookworm infections are reduced and lost in the absence of re-infections. Most of the published evidence indicates that the percentage of infection slowly decreases for several years, the drop being more rapid after five or six years, although cases of infection persisting for at least fifteen years in the apparent absence of re-infection have been recorded. Having found that reliable estimates of the degree of infection in groups can be obtained by means of estimation of eggs per gramme of fæces, egg-counts were made on 915 prisoners in the Alipore Central Jail for various periods of time under conditions which made the probability of re-infection very slight, if not completely absent. This investigation disclosed the fact that about 50 per cent. of the original infection is lost within three months, 60 per cent. in six months, 70 per cent. in one year, 80 per cent. in two years, 90 per cent. in four years, 93 per cent. in six years and 95 per cent. in eight years. Some slight infections were found, however, up to twenty years after imprisonment, but the possibility of *some* infection having occurred some time during this period cannot be excluded. This rate of reduction in egg output corresponds very closely with Mhaskar's figures on worms harboured by prisoners in the Trichinopoly Jail after various periods of imprisonment. Investigations on the correlation between worms harboured and eggs per gramme of fæces after different durations of infection, as well as the evidence furnished by Mhaskar's worm-counts, indicate that there is no appreciable falling-off in rate of oviposition with increasing age of worms, and that the drop in egg output is due to an actual loss of worms.

Evidently only a small percentage of worms which reach maturity in the intestine succeed in settling themselves in favourable locations, or else they have habits which make a long life improbable.

When unfavourably located, they apparently remain in the intestine for only a few weeks or months. Smillie's conclusion that hookworms are slowly acquired and slowly lost, based on the progressive slow increase of infection with age, does not appear to be tenable. It appears rather that the worms are rapidly acquired and rapidly lost, which results in the establishment of a similar equilibrium in a community. The slow rate of *net* acquisition of hookworms in children can be explained on the basis of habits. The rapid acquisition of hookworms after treatment when no precautions are taken against re-infection confirms this view.

Acute Mercuric Chloride Poisoning (L. A. Kohn, *Archives of Internal Medicine*, February 15, 1926).—Death from mercuric chloride taken by mouth may ensue within a few hours, from circulatory collapse, with little renal damage and no evidence of uræmia. Evidence is presented which suggests that direct myocardial damage may account in part, at least, for this early toxic death. In three severely poisoned cases, the white count reached 34,000 or higher in a few hours, and it is suggested that the degree of elevation of the leucocytes may be an index of the severity of poisoning with an unfavourable prognosis when levels of from 30,000 to 40,000 are found. While it is not denied that sodium thiosulphate may have value in treatment, it should be emphasized that it may fail to exert detoxicant action, and should not be administered to the neglect of established therapeutic methods.

On the Rate of Multiplication of Rabies Fixed-virus in Rabbits (J. W. Cornwall and W. A. Beer, *Indian Journal of Medical Research*, January, 1926).—Experiments have been carried out at the Pasteur Institute, Coonoor, with a strain of fixed-virus in its 940th passage. If this virus be subpassaged in rabbits, each subpassage animal being killed on the third day, the series cannot be continued beyond the second subpassage. If each subpassage animal be killed on the fourth day or later, the series can be continued indefinitely with no increase in the length of the incubation period. The rabies fixed-virus, therefore, does not multiply at such a rate that 0·01 grm. of brain substance can carry a lethal dose of it after two subpassages performed on the third day, but 0·01 grm. brain substance will always contain a lethal dose if the subpassages be made on the fourth day or later.

Certain Observations on the Mechanism of Quinine Hæmoglobinuria in Man (U. N. Brahmachari, *Indian Journal of Medical Research*, January, 1926).—A case is described in which the patient was accustomed to take quinine for attacks of malarial fever from which he was suffering from time to time but this was the first occasion on which he had hæmoglobinuria. The attack of hæmoglobinuria was of an intermittent nature, increasing during heights of fever and diminishing during apyrexia. During the stage of active hæmolysis, hæmolysis was going on in the liver just as in the case of quinine hæmoglobinuria. Though the patient gave a history of malarial attacks, he was found to be suffering from kala-azar. This is the second case in which hæmoglobinuria was manifested in a case of kala-azar.

Original Communications.

OTES ON A CASE OF BRONCHOMYCOSIS.

By N. Chyurlia, M.D., Venice.

Mrs. N. N., an Italian woman, aged 42 years, ho belonged to a wealthy family, had suffered most continuously since childhood from bronchial tarrh. There is nothing worthy of note in the mily history. When she was eighteen years old e expectoration, which hitherto had been muco-rulent, became hæmorrhagic. At the age of 23 e married, and was left a widow three years later. he had two abortions, one at the second month d the other at the fifth month of pregnancy. In 19 she had a severe attack of influenza, localized the left lung, from which she completely re-vered. Many years of ill-health followed, and the tient had consulted several doctors. All agreed at she was suffering from chronic bronchitis. Some ggested the existence of cavities in the right ng; others noted symptoms of emphysema. Some vised mountain air, others the seaside. Hypho-ycetes and saccharomycetes were found in the utum. The patient followed all this advice, and so for years took balsamics, together with large ses of alkaline iodides (120 to 150 drops a day). At the end of 1922 the patient came under my bservation, and during 1923-1924 her condition owly but greatly improved.

Symptomatology.

(Excluding the Circulatory and Respiratory Organs.)

There is evidence of some deficiency in the general utrition, and the facies is constantly congested and yanosed.

The patient often presents slight rises of tempera-ure, subfebrile in character, and not preceded by igors nor followed by sweating, and lasting only a w hours. She takes good food; menstruation com-enced at fifteen, and the catamenial function is lways regular. The stomach, intestines, and the ver are normal, and the intestinal function is tonic. The spleen is normal and there is no renal tosis. The density of the urine is between 1,014 nd 1,020; and the urea is between 16·7 and 22·4 rm. per thousand. On rare occasions uric acid as been found, but never more than 0·40 per ent., and slight traces of indican. Constant ab-ence of albumin, peptone, glucose and other ehling-reducing substances. Mineral salts are in ormal proportions. The microscopical examina-ion of the urinary sediment showed scanty eucocytes, the usual histological elements of the rinary tract, sometimes small crystals of calcium xalate, of urates and of phosphates; and there are o signs of inflammation of the kidneys.

Symptomatology of the Circulatory and Respiratory Organs.

The pulsation of the apex of the heart is placed slightly to the left and the heart-beat extends out-wards. On percussion the cardiac dullness is en-larged through slight dilatation of the right ven-tricle. At auscultation accentuation of the second sound is noted. There are no murmurs to alter the clearness of the sounds in all sites of auscultation. The radial pulses are synchronous, a little distended, and the hypertension is confirmed by the fact that in the horizontal position of the body the number of the pulsations increases from four to six a minute compared with those with the body in the vertical position. The superficial venous system is much developed and passively congested.

Examination of the blood showed 3,800,000 red globules. The leucocytic formula presented the following percentages: Polynuclear neutrophils 77 per cent., polynuclear eosinophils 3 per cent., lymphocytes with azurophil granulations 3 per cent. Türck's cells 3 per cent., Rieder's cells 0·50 per cent., lymphocytes 4·59 per cent., lymphoid erythroblasts 1·50 per cent., plasma cells 1·50 per cent., transitional cells 2·50 per cent., mononuclears with eosinophil granulations 1·50 per cent.

The thorax is well-formed, cylindro-conical in shape. In the respiratory movements the right hemithorax does not follow the whole course of the left hemithorax. On percussion the sound is clear all over the thorax, rather higher on the left; but on the right beginning from the higher level of the eighth rib on the paravertebra and of the higher margin of the sixth rib, the sound becomes obtuse, passing immediately from a clear sound to absolute silence. The respiration is costal. There is no thoracic pain, neither spontaneous nor provoked. Râles are heard all over the right thorax. In the upper part of the right lung, along the internal margin of the scapula, the respiration is harsh, mixed with whistling sounds, especially on inspiration. Until last year the patient's respiration was noisy and could be heard at a distance; the voice was hoarse, and there was sometimes aphonia, gurgling râles, shortness of breath, and an almost permanent sensation of burning in the throat. Often the patient noticed the smell of fermentation in the breath, similar to the fermentation of beer, or sometimes, especially after expectorating, there was a sweetish taste and a putrid odour. The quantity of expectoration increased during the 24 hours (up to 400 500 c.c., and sometimes much more).

In a glass vessel the expectoration separated into three layers: the top layer was greenish, very thick, flaky, composed of thick sputum strongly adherent to the walls of the receptacle, it left on the glass a whitish line, opaque, scarcely soluble in water, and made up of deposits of fatty acids. It was this upper layer which had the characteristic aromatic, ethereal smell of fermentation. The middle layer was clear like water. The bottom layer had a granular aspect, homogeneous, it was often sprinkled with large, greenish, purulent, thick, compact flakes. Sometimes the expectoration was of a uniform slate-grey colour, other times yellow-reddish, almost orange colour, and very rarely the presence of unaltered blood could be seen. Cough was very frequent, especially at night; often it was harsh, dry, with difficult emissions of mucus, at times easy; fat followed by abundant expectoration was vomited.

These symptoms slowly disappeared, and during the last two years, having undergone a severe and appropriate treatment, the patient has greatly improved. The expectoration is reduced to a few cubic centimetres in 24 hours, the cough is rare, respiration easy, deeper, cannot be heard at a distance; the râles are limited to the base of the right lung, whilst the fermentation and the putrefaction have completely disappeared.

Microscopical Findings in the Expectoration.

Investigations relative to the pathogenic agent from a therapeutic point of view can be divided into three periods. The first period, very long, comprises all the years of the patient's illness up to 1922. During this time microscopical researches on the expectoration were scarce and uncertain. It seemed sufficient for the doctors to exclude Koch's bacillus, and only very recently the presence of a hyphomycete was verified (not defined or characterized) in the sputum. The second period is from the end of 1922 to August, 1924. During this time the patient was under my care. During this period about 40 examinations of the expectoration were made. These examinations not only confirmed the exclusion of Koch's bacillus, but admitted the constant presence of a blastomycete (saccharomycosis) well stained by Nicolle's method, Gram-negative, made up of numerous ovoid or ellipsoid corpuscles, often united at the polar extremity, surrounded by capsules, with protoplasm finely granular, and sometimes vacuolated, about 3 or 4 microns × 5 to 7 microns in size (Koritska ob. 1/15 in. semi-ap. ad. imm. ocul comp. 4). I was certain, therefore, that the case was one of blastomycosis. From September to December, 1924, the patient was in the hands of another doctor, who prescribed 24 injections of autovaccine without any appreciable results. In December, 1924, the third period began. Frequently at the microscopical examination of the expectoration very fine filaments could be seen, often mixed with roundish corpuscles. Their presence coincided with a larger number of small, round cells of the bronchial epithelium and with the periods of recrudescence of the clinical symptoms.

I had already carried out some cultures with the sputum, on Sabouraud's agar, in which a germ was detected and suspected to be a monilia. This doubt was cleared up by the mycological diagnosis of the eminent Professor Castellani, who confirmed the presence of *Monilia krusei* (Castellani 1909).

The mycological and bacteriological investigations, the experiments on animals and the experimental therapeutic tests have now been handed over to Doctor Redaelli.

Therapy Used.

It is impossible to describe all the means used. A precise idea can be gathered from the fact that for many years of the first period, up to 1923, the patient had made great use of balsamics, and alkaline iodides by the mouth. From 1923 to August, 1924, I had given large doses of iodide in the form of daily injections of sidiodal and of oil-iodine simple and guaiacolated, together with inhalations of balsamics. By this treatment the condition of the patient was remarkably ameliorated. During September-December, 1924, autovaccine injections gave no results. I advised the use of a special autovaccine according to Steinfeld, the use of alkalines by the mouth, which proved very efficacious, the application of ultra-violet rays, the continuation of the iodides and the other therapeutics which might be suggested from the experimental studies. All this is now being done, and good results have already been obtained.

LEPROSY IN A FOURTEEN MONTHS OLD CHILD.

By E. A. Neff,

Medical Superintendent, Leper Station, Makogai, Fiji.

All authorities, I think, agree that leprosy is a disease that rarely attacks those under five years of age. The youngest case I have seen hitherto reported was that of a child aged nineteen months and described by Drs. William J. Goodhue, Medical Superintendent, Malokai Leper Settlement, and George W. McCoy, Director United States Leprosy Investigation Station, Hawaii, in *Public Health Bulletin*, No. 75, of January, 1916.

The history of the case is as follows: A female child (Alexandrina) was born at this station on December 5, 1923. The mother, an Indian, being a well advanced nodular leper and the father a healthy Indian of perhaps 23 years of age. The mother was admitted pregnant. At the birth of her child the mother's disease was particularly active, and since her admission in June, 1923, she had not responded to treatment. The confinement was normal, as was the puerperium. Almost immediately following her confinement, the mother had a very severe reaction with fresh and extensive infiltration of the skin. This was followed shortly by two or three milder reactions. On account of the child's delicate state of health during this time she was allowed to nurse it until this was precluded on account of leprotic infiltration of the nipples.

The mother has a sister here, a mixed leper. She has one other child, a boy aged four years, who has not developed leprosy.

The patient has never been a robust child, but has developed along normal lines. The only diseases she has had, other than this, are a mild attack of dysentery and scabies. On February 12, 1925 arrangements had been made whereby she was to be sent to her father, in Levuka, when a papular nodule was noticed in the centre of her left cheek (it is quite certain that this lesion had been present for at least three months, but had not shewn typical and so had not been suspected). This was incised and a smear taken, which, when examined, showed all fields filled with acid-fast bacilli in characteristic grouping. Nasal smears taken on this date from each nostril were negative. Examination of her skin showed several very small depigmented areas

over her right shoulder and over her back. These, in my opinion, were not leprotic. Otherwise skin findings were negative. Repeated examinations of this nodule, which gradually increased in size, showed bacilli until July 15, when nothing could be demonstrated. In connection with nasal smears it is interesting to note that repeated smears were negative until February 21, when each nostril showed highly positive, the bacilli being typical, numerous, and in definite grouping. On July 7 two new very small nodules appeared, one just external to the left eye, and the other in front of the right ear.

TREATMENT.

Weekly intramuscular injections of Burroughs Wellcome's "moogral" have been given to her throughout in 1 c.c., increasing to 2 c.c., doses. The drug has latterly been given in combination with olive oil, camphor, and resorcin.

Since September, 1925, her disease has remained stationary and inactive, and she has been bacteriologically negative. The initial nodule shows as a typical scar, the size of a shilling, and the marks of the smaller nodules can scarcely be seen, so small are the scars.

Dr. ALDO CASTELLANI has just returned from America where, at the invitation of the authorities of the Tulane University, New Orleans, he has established and organized a tropical medicine division in the medical school. During his visit he had the honour of being invited to deliver the Gehrman memorial lecture series at the University of Illinois; and later, at the Annual Convention of the American Medical Association and its Medical Exhibition on scientific subjects, he was awarded the Gold Medal, the highest recognition which can be given by the association. The award "was based on the excellent investigation in comparatively unexplored fields of medicine and for the perfection of the display" of specimens.

Intravenous Administration of Sulpharsphenamin in Syphilis (M. F. Lautman, *Archives of Dermatology and Syphilology*, February, 1926).—In cases of syphilis which are Wassermann-negative and free from clinical symptoms, sulpharsphenamin seems quite as capable of controlling the disease as the old arsenicals. From personal observations by the author as well as the observations of others, it seems that sulpharsphenamin in neutral syphilis is even more effective than arsphenamin or neo-arsphenamin. Given intravenously, sulpharsphenamin did not produce dermatitis and caused practically no constitutional reactions. On account of the absence of disagreeable reactions, patients submit more willingly to treatment with sulpharsphenamin, and, consequently, it is indicated in cases in which the maximum spirochæticidal effect of arsphenamin and neo-arsphenamin is not essential.

PUBLIC HEALTH ON THE GOLD COAST.

IN 1914 the staff of the Sanitary and Public Health Department of the Gold Coast consisted of eight officers, whereas to-day it comprises seven

officers only. As Sir William Simpson[1] points out, this organization for a country the size of Great Britain is obviously insufficient, and that although even with this small staff much good work has been done, it is, nevertheless, too small to secure continuity of policy or the progress that is needed. The necessary periodical leave also leads to frequent transfers, so that extra work under pressure is thrown on to others who have to carry on the duties. In addition to an increase in the numbers of the present staff it is also suggested, at least as a beginning, that one inspecting health officer should be appointed for each province. There are three provinces in the Gold Coast Colony and two in Ashanti, the Western and Eastern Province, but the Eastern Province is so large that it could advantageously be divided into two administrative health areas with an administrative health officer in each. The mandated territory of Togoland must also be considered, and this would also require at least one provincial health officer. Thus, providing for leave nine of these officers would be required. As regards the Northern Territories, however, the provision of health officers might be deferred until the suggested inquiry into the conditions of health of these territories has been completed.

It is suggested that it would be the duty of these provincial health officers (1) periodically to visit and inspect the towns in which medical officers of health and medical officers are located in his province; (2) to inspect from a health point of view the conditions under which labour is being carried out in large works, such as railways, harbours and road construction and in the numerous mines that are being opened up, and which have no medical officer responsible for the welfare of the workers; (3) to arrange that borrow-pits caused by railway construction at stations where villages and towns have sprung up, to be drained and filled up; (4) to visit the districts in their province during the cocoa season and keep a watch on new centres of trade springing up; (5) to visit the more important villages and assist the district commissioner in the endeavour to encourage the chiefs to have their villages cleaned up and built on suitable lines; (6) to visit and inquire into the source, advise and assist the medical officers of health in any outbreak of an epidemic or infectious disease such as plague, yellow fever, cerebro-spinal fever, small-pox, &c., which occurs in the province.

At the same time there should also be a closer association between the engineering and sanitary services and between the Medical Research Institute and the sanitary services than exists at the present time. It is unfortunate that the excellent laboratories in Seccondee are at present closed on account of shortage of staff. The dearth of expert staff in the laboratories is specially dangerous for a seaport where bacteriological, pathological and chemical investigations safeguard against outbreaks of disease, where facilities are also required for the bacteriological and chemical examination of drinking water and food-stuffs, and where the diagnosis and treatment of doubtful cases can only be cleared up by a laboratory report.

Branches of the Medical Research Institute at Accra are needed and should be adequately staffed at Seccondee, Coomassie and Cape Coast.

For the more effective prevention of the spread of epidemic disease such as plague, yellow fever, cerebro-spinal fever, small-pox and other important infectious diseases, it is essential that every department of the public health in the colony should be informed as soon as possible of their occurrence and the locality affected.

Lastly, Sir William Simpson also suggests that a weekly bulletin giving the name and number of each infectious disease occurring in each locality should be issued by the Central Health Office to the medical officers of health, the provincial health officers, the laboratories of the Medical Research Institute and its branches, and to the senior medical officers in the different towns and stations, and, where there is no medical officer, to the District Commissioners. If there can also be added similar information regarding the existence of these diseases in countries adjacent to and in communication with the Gold Coast it would greatly add to the value of the bulletin.

[1] Report to the Secretary of State for the Colonies on the Sanitary Condition of the Mines and Mining Villages in the Gold Coast Colony and Ashanti. By Professor Sir William Simpson, C.M.G., M.D., F.R.C.P., D.P.H. Published for the Crown Agents for the Colonies, 1925.

Annotations.

The Destruction of Rat-Fleas by Heat on Board Ship (R. K. Shaw, *Journal Royal Naval Medical Service*, October, 1925).—The experiments reported were conducted on board H.M.S. *Endeavour* during February and March, 1925, the ship being then engaged in surveying duties off the West Coast of Africa. The fleas used in the experiments were obtained by bringing on board some thirty black and brown rats, killing them and combing out the fleas. Although the available material was not large, the experiments admit of the following conclusion: All rat-fleas are capable of being destroyed in a dry blanket (not more than twice folded) if exposed to a temperature of 110° F. for a period of three hours—such a temperature was found to be constantly present in various parts of the engine room in H.M.S. *Endeavour* while at sea. Fleas are able to withstand a high temperature for a prolonged period if kept moist. This resistance is not due entirely to the action of moisture in delaying penetration of heat. If blankets and clothing are quite dry and so arranged as to give free access of air at a minimum temperature of 110° F. to every portion of the articles, rat-fleas on such articles will be killed within a period of three hours. This method of killing fleas has proved to be of practical value on such a ship as the *Endeavour*. It would be of interest to ascertain whether other ships provided similar facilities.

An Outbreak of Rat Poisoning probably due to Rat Virus (R. S. Spray, *Journal of the American Medical Association*, January 9, 1926).—The epidemiologic evidence, confirmed by bacteriologic and serologic findings, indicates that the outbreak of 123 cases of acute gastro-enteritis among the girls eating at the women's hall of West Virginia University and of twelve cases among the kitchen personnel, was due to contamination of some food with a commercial rat virus, which was distributed just sixteen days previous to the outbreak. Paratyphoid bacilli of the same type were alive in the original bait on the serving room floor twelve days after the outbreak. Flies and ants were abundant and had access to the baits as well as to the kettle in which the bait was prepared. In addition, at least three persons mopped the floors daily with hand-wrung mops, which undoubtedly had contact with the baits, and from this duty went directly to the preparation of foods. The epidemiologic evidence indicated that milk, or milk and cream, was the probable vehicle of the infection. If milk was responsible, the contamination evidently occurred subsequent to delivery from the dairy. The isolation of a recognizable organism from fourteen students, and the identity of these strains, in all respects tested, with organisms isolated from the rat bait and with the rat virus from the commercial package, serves to support and corroborate the other evidence.

Studies in the Common Cold. I. Observations of the Normal Bacterial Flora of Nose and Throat with Variations Occurring During Colds (G. S. Shirley, F. M. Hanger, and A. R. Dochez, *Journal of Experimental Medicine*, March 1, 1926).—The normal bacterial flora of the nose and throat of thirteen individuals has been studied over periods ranging from five to nine months. Observations have been made by the authors of qualitative and quantitative changes in the flora occurring in the course of colds and of throat infections appearing in the group. The normal basic nasal flora includes *Staphylococcus albus*, diphtheroids, and for certain individuals *Staphylococcus aureus* and *B. influenzæ*. Occasionally transient bacteria and Gram-negative cocci and non-hæmolytic streptococci. The normal basic throat flora includes Gram-negative cocci, non-hæmolytic streptococci, and for certain individuals "large Gram-negative cocci," *Bacillus influenzæ*, Bacillus "X," and diphtheroids. Transient organisms are *Staphylococcus albus*, *B. mucosus*, and pneumococci. No bacteria were found in early cold cultures to which a causative rôle could be assigned. In the course of colds the basic flora of the nose was often scanty in the early stages. The throat showed reduction of prominence or alterations in predominance of the basic flora. Certain organisms were prominent in colds, usually as late or secondary invaders: these included *Staphylococcus aureus*, hæmolytic streptococci and *B. influenzæ*. There was a striking increase in the incidence of hæmolytic streptococci in throat infections.

Effect of Compound Solution of Iodin and Rest in Surgery of Exophthalmic Goitre (H. M. Clute, *Journal of the American Medical Association*, January 9, 1926). Compound solution of iodine has been used in the treatment of two hundred cases of primary hyperthyroidism in the Lahey Clinic. A study has been made of the effects of this treatment in this group of cases, of which sixty-nine have been especially selected for detailed presentation. Rest in bed from seven to ten days before operation is of great importance in pre-operative preparation. Before the use of compound solution of iodine and rest in bed, only 38 per cent. of the patients were operated on in one stage. Since the use of the solution and rest in bed preoperatively 63·7 per cent. have been operated on in one stage. The number of pole ligations has decreased from 51 per cent. in the past to 13 per cent. in this series of cases. In the eighty-five cases of primary hyperthyroidism in which operation was performed during the first five months of 1925, no pole-ligation has been necessary. Of the patients in this group 7·2 per cent. failed to show an appreciable drop in metabolic rate after the use of the solution and rest. The results following subtotal thyroidectomies are similar. Iodine administered over long periods without thyroidectomy does not cure exophthalmic goitre. Thyroidectomy must be added to produce a complete return to normal health.

Cutaneous Reaction in Leishmaniasis (Joao Montenegro, *Archives of Dermatology and Syphilology*, February, 1926).—Intradermal injections of an alkaline extract of *Leishmania* were given to thirty-seven patients with leishmaniasis, and positive reactions were obtained in thirty-two or 86·5 per cent. Injections with the same extract were also given to thirty-six persons free from leishmaniasis. Of these, thirty-three developed negative reactions and three showed a certain reaction definitely distinct from the specific reactions obtained with the patients who had leishmaniasis. It was much less intense. The cutaneous reaction of leishmaniasis is specific, and for this reason when typically positive is of itself sufficient to confirm the diagnosis, if the patient has never had leishmaniasis before. A negative reaction reduces to 13·5 per cent. the possibility that the disease is leishmaniasis. The result of the reaction should not be accepted without knowledge beforehand concerning the specific value of the extract. Positive reactions were obtained in all stages of healing. The extract prepared from a strain of *Leishmania tropica*, or oriental sore, provoked a specific reaction in the bearers of the Brazilian type of *Leishmania*.

This argues in favour of the unity of the alleged species. There has been no opportunity to produce the cutaneous reaction in patients cured of leishmaniasis.

Report.

MALARIA-CONTROL IN CEYLON PLANTATIONS.[1]

By Sir RONALD ROSS, K.C.B., K.C.M.G., F.R.S.,
Director-in-Chief, Ross Institute and Hospital for Tropical Diseases, Putney Heath, S.W. 15.

ON October 26 last year I addressed the Ceylon Association regarding Malaria-Control in Tropical Plantations. I was obliged to speak on the general subject because I then possessed little experience of the local conditions in Ceylon—with which we are specially concerned; but I emphasized the importance of malaria-control in warm climates and urged that the only way to achieve it in tropical plantations is for the affected plantations to organize a system under which they can always obtain expert advice regarding their own particular problems of defence. Following upon this lecture it was suggested that I myself should go to Ceylon in order to study the subject at first hand. The Ross Institute, which has been founded for such purposes and has received much welcome support from Ceylon, assented; and the expenses were generously guaranteed by the Colombo Commercial Company; by Messrs. Rowe, White and Co.; by the Ceylon Tea Plantations Co.; by Messrs. Harrisons and Crosfield; and by the Grand Central (Ceylon) Rubber Estates. Consequently, I left Liverpool by the Bibby Line on December 11, 1925, and arrived at Colombo on January 4, 1926. I remained in Ceylon for more than six weeks, left Colombo on February 17, and returned to London via Marseilles on March 7.

On arrival in Ceylon I received a very kind welcome from His Excellency the Governor, Sir Hugh Clifford; from the Hon. Dr. J. F. E. Bridger, Principal Civil Medical Officer; from Mr. H. F. Carter, the Government Malariologist (who had been with me at the Liverpool School of Tropical Medicine years previously); and from many other gentlemen. Next day, Mr. W. Forsythe (a member of the Council of the Ross Institute) and Mr. C. D. Sparkes took me for a preliminary survey of estates in the Kelani Valley; and on the same day I gave an address to the Ceylon Estates Proprietary Association at Colombo, Mr. G. C. Slater in the chair. On January 8 I addressed the Planters' Association of Ceylon at Kandy, Mr. J. W. Oldfield in the chair. Meanwhile, my tour among the estates was arranged by Mr. Slater, Mr. Forsythe, and Mr. C. L. Carson-Parker; and during the tour I was invited to address the planters at Tebuwana Club on January 16; at Kaluganga Gymkhana on January 20; and at Ratnapura on January 30. My warm thanks are due to the kind hosts who entertained me during the tour—to Mr. H. W. Roy Bertrand at Govinna Estate; to Mr. and Mrs. E. C. Hawkins at Dumbara Estate; to Mr. E. Gordon Brooke at Hanwella Estate; to Mr. and Mrs. A. J. Ingram at Pelmadulla Estate; to Mr. and Mrs. C. de E. Collin at Pitiakande Estates; to Mr. J. Sheridan-Patterson at Delwita Estates; and to Mr. H. D. Garrick (to whose enthusiasm for the Ross Institute it is so much indebted) at Ukuwela. I am also much obliged for hospitality and also for information to Mr. and Mrs. Slater; to Mr. and Mrs. Oldfield; to the Hon. Mr. and Mrs. Kindersley at Kandy; the Hon. Mr. T. L. Villiers, Mr. John Still, Mr. Blythe, Mr. and Mrs. Wedderburn, and Mr. Sudbury at Anuradhapura, and to other obliging friends. At Anuradhapura, Mr. Carter, the Government Malariologist, and Mr. W. H. Schokman, who assists him there, showed me their careful and successful mosquito-control works now in course of elaboration. Before departure, I broadcasted on the subject of malaria at the Central Telegraph Office, and again addressed the Ceylon Estates Proprietary Association on February 15; and lastly, received the hospitality of their Excellencies, Sir Hugh and Lady Clifford at Colombo. My only regret is that want of time compelled me to decline some invitations to lecture and obliged me to forgo calling upon some gentlemen whom I particularly wished to see. I am also much indebted to Sir James Lochore and to Mr. W. Shakspeare (Vice-Chairman of the Ross Institute) for valuable assistance; and last, but far from least, to Mr. G. H. Masefield for his fully-informed and whole-hearted support of malaria-control in Ceylon, as well as for organizing my visit there.

It will be unnecessary for me to repeat the general remarks on malaria which I made before the Ceylon Association last October; but it is advisable to re-emphasize some points there dealt with. One cannot say that beyond a few special anti-malaria campaigns here and there, the British Empire has fully utilized even yet the discovery that malaria is carried by *Anopheles* mosquitoes—which was made in 1898-99, more than a quarter of a century ago. The explanation of this delay is that, theoretically, malaria may be prevented in several different ways (namely, by the use of mosquito nets, by the application of "culicifuges" to the skin, by the regular taking of quinine, by segregation, and by the general method of mosquito-control) so that sanitary officers have been divided by their own embarrassment of riches in regard to malaria-prevention: some have preferred one method and others have preferred another method, while the Governments of our tropical dependencies have never been able to allot large enough funds for any of such works on general scales. The great successes against malaria, namely, those in the Federated Malay States, in the Panama Canal zone, and in the Suez Canal zone, have been effected by wealthy companies

[1] A report delivered to the Ceylon Association, London, on April 9, 1926.

rather than by Colonial administrations; and Governments can scarcely be expected to allot large sums until a full decision has been reached regarding the best manner in which to employ those funds.

During the whole of this "negative phase," however, there has been a steady advance in one direction, due partly to enthusiastic medical men and partly to well-trained entomologists—I mean the determination of the exact species of mosquitoes which carry malaria in different countries and the detailed observation of their habits, their breeding places, their seasonal prevalence, and their capacity as carriers of the disease. These studies have been set forth in a number of admirable scientific publications—which, of course, are little known to the general public. It cannot be any longer pretended, as was pretended twenty years ago, that we do not possess sufficient knowledge of mosquitoes to justify us in spending money for controlling them. But, as I have said, though we have now obtained all or most of the knowledge necessary for mosquito-control, yet the final stage of active public mosquito-repression has scarcely been reached even now.

But there is one direction in which I have observed a very distinct improvement. Apart from the *Anopheles* mosquitoes which carry malaria, there are in the tropics, as everyone knows, a number of domestic species belonging chiefly to the genera *Culex* and *Stegomyia*, which commonly infect all human dwellings and which cause much annoyance to human beings, while they even sometimes carry dengue, yellow fever, and filariasis. The whole time that I was in India, from 1881 to 1899, I always observed that these species tended to swarm in private houses, hotels, and even in hospitals; and I frequently estimated that, in spite of mosquito-nets, punkas, fans, and thick socks, I was bitten at least two or three times every twenty-four hours by one species or another. In some places the plague of mosquitoes became more than a mere annoyance—for instance, I remember my own miserable experiences when I stayed for a night in a Colombo hotel in the year 1888. The insects abounded everywhere in the tropics. They would bite one's ankles at dinner parties and would show extreme intelligence in entering mosquito nets with the smallest holes in them. Even so late as 1902, when Sir William McGregor and I stayed in the Suez Canal Company's houses at Port Said and Ismailia (whence the mosquitoes have now been banished) we were plagued almost beyond endurance by them. I have not visited India again since 1899 (except for a week's stay at Bombay in 1908), until the visit to Ceylon now being dealt with; and I notice an immense change in this respect. During the whole six weeks of my stay I do not remember to have been bitten once (though I am a very popular subject of mosquitoes' attentions), and I saw only about six mosquitoes the whole time, during which I resided in four large hotels and in seven planters' houses, and visited several other buildings. Doubtless the domestic mosquitoes still continue to abound in many private houses, in native huts and habitations, and elsewhere; but the improvement already manifest in the hotels and other places mentioned is a welcome augury for the future. The mere comfort of life in the tropics is vastly enhanced by the absence of these little pests, the common domestic mosquitoes. The improvement has been due simply to the spread of knowledge. Nearly everyone in the tropics now knows that mosquitoes may carry diseases and that they breed largely in gutters, in pots and tins round houses, in water-butts, and in roof-gutters. Intelligent persons can reduce the plague in their own houses in many places, though certainly not in all. The improvement has been a subconscious one, which can scarcely be detected except by those who, like myself, have had a long previous experience of tropical life.

Malaria, however, is not carried by these domestic species of mosquitoes, but by the *Anopheles*, most of which breed in natural ground-waters apart from habitations or not necessarily close to them. No single householder can decree the banishment of *Anopheles* from his house simply by looking after his own premises. For *Anopheles* concerted public action is necessary. And now I have great pleasure in recording the admirable work done recently in Ceylon by the Public Health Department of the colony, especially by Dr. Bridger and the malariologist, Mr. Carter. Mr. Carter was appointed only a few years ago, but has already done an immense amount of detailed, but necessary, researches on the mosquitoes in the island, especially the *Anopheles*. His office in Colombo is a useful, though not a large one; and it has been collecting extensive records of the habits and distribution of the insects—with the assistance of several capable workers. Carter's brochure on the "Anopheline Mosquitoes of Ceylon" (*The Times of Ceylon* Co., Colombo, April, 1925) is a brilliant little compendium, and his reports already published in the "Annual Report of the Medical Department, Ceylon," for 1924, pages 3 and 53, give much exact knowledge necessary for malaria-control throughout the island. During my visit he was engaged upon writing a still fuller report; and I am glad to hear that his services are to be continued in the colony. We may be convinced that under Dr. Bridger the work of malaria-control will be pushed as far as funds and circumstances allow. In fact, the malariological department is another advance far beyond anything which I saw in the East before I left it in 1899. With enlargement, with more generous financial support, and with the more enlightened assistance of the whole public in Ceylon, it will, I am convinced, effect a very great improvement as regards malaria throughout the colony.

Another piece of work done by Mr. Carter has been to make an estimate of what are technically known as spleen-rates in Ceylon. This test consists in ascertaining the proportion of people in any locality who show enlargement of the spleen—a pathological condition due, with rare exceptions, in Ceylon only to malaria. I need not discuss the method here. It has been employed throughout the tropics for many years. Roughly speaking, the

larger the spleen-rate, that is, the greater the proportion of people with enlarged spleen in a locality, the greater the rate of malarial infection in that locality. Further refinements are obtained by noting the average sizes of enlarged spleens in the inhabitants; and the test is specially valuable amongst the new comers, that is the children. Mr. Carter has prepared many maps showing the spleen-rates in very many areas all over Ceylon, and I was able to verify some of these rates in the neighbourhoods visited by me. From these it appears that malaria is most prevalent, as he says, in the plains to the north and east of the central mountain mass; and this fact is largely, if not quite fully, explained by the special prevalence of the malaria-bearing species of *Anopheles* in the affected districts.

All these are technical matters which it is unnecessary for me to discuss here, as they have been already fully dealt with in the reports of Dr. Bridger and Mr. Carter. I myself was concerned specially with malaria in the plantations, and the best organization for dealing with it. Here we may remark, to begin with, that the official Malaria Department, appointed and paid for by Government, is necessarily concerned chiefly with the towns and villages of the general population. As with sanitary departments elsewhere, it cannot with its present income and organization deal fully with private estates, that is, with large rural areas distinct from the civil population. Government keeps an eye on housing schemes, general sanitation, hookworm disease, and other communicable maladies; but the public funds now available will scarcely suffice for anti-malaria sanitation for the whole of the 25,365 square miles in the island. The main point for me to consider, then, in reporting upon malaria-control on private estates in Ceylon was concerned with the best organization for this special purpose.

Two courses appear to be open to the planters, namely:—

Scheme A.—To contribute funds to the Colonial Malaria Department in order to enable it to inspect and advise upon malaria-control for every malarious plantation, as well as for the general population.

Scheme B.—To appoint one or more Plantation-Malariologists for the special purpose of dealing with plantation-malaria—to work, of course, in touch with the Government Malaria Department as much as possible, but to be supported by the estates.

I had several conversations with Dr. Bridger and Mr. Carter on these points, and also consulted the Office of the Colonial Secretary about them. Regarding Scheme A, there appears to be some difficulty as to whether Government would accept *ad hoc* contributions from any private properties. This point could not be decided during my brief visit; but, personally, I should think that arrangements ought to be quite feasible, given goodwill on both sides. The Colonial Malaria Department would have to survey all the malarious estates in order to detect the breeding areas of the mosquitoes, and would then have to advise and help managers of the estates as to how best to deal with these breeding areas. This would imply merely an enlargement of the staff of the Malaria Department enabling it to cover the estates as well as the towns and villages of the general population. What I had in mind under this heading was that the planters might contribute an annual sum to the colonial revenue, but ear-marked for the express purpose of malaria control in the plantations, in order to provide as many assistants to the Colonial Malaria Department as it would require to enable it to deal with the malarious estates. But this would involve certain administrative difficulties between the planters on the one side and Government on the other, and I was not sure when I left Ceylon that these administrative difficulties could be overcome.

If they cannot be overcome, then the planters should take steps to appoint special malariologists for looking after their own estates (Scheme B)—as has been done so successfully by the planters in the Federated Malay States, assisted by Sir Malcolm Watson, Mr. C. Strickland, and other gentlemen there. Under this heading I should strongly advise the planters to acquire the services of at least one active, fully-trained and qualified European to advise all the malarious estates, with necessary assistance. Unfortunately, the number of such men available is by no means large at the moment. I fear I can suggest only a few names, while men who are sufficiently qualified for the work and also possess a knowledge of local conditions in Ceylon are very few indeed. Whoever is appointed must be given a proper salary, with sufficient tenure, and some arrangements for a pension, because a short-time man will scarcely be able to throw his whole heart into the subject. He must be provided with a house at a central spot, a motor car, and also a small laboratory; and will certainly need some native assistants, and perhaps even a European one later on, at least during the malaria season. His work will be fairly heavy until he has made accurate malaria surveys of the affected properties, and his time should not be spent on hospital or other medical practice; but perhaps other sanitary duties in connection with the estates may be entrusted to him subsequently—so that he might ultimately develop into an Estates' Health Officer. Several of us who considered the matter together thought that the cost would be about £2,000 a year, at least. This would be exclusive of the cost of the actual mosquito-control measures, which would have to be borne, when possible, by each affected estate for itself. Whether Government would render financial help for Scheme B I cannot say, but it may be asked for.

On the other hand, Scheme A might cost the planters less because their malariologist would be already provided by the Government Health Department and the estates would have to pay only for such assistants as he might require for inspection and supervision in them. In both cases they will probably have to pay at least part of the cost of the actual mosquito-control measures, whatever these may be.

I laid these alternatives before the Ceylon Estates Proprietary Association before my departure; but

iscussion regarding them was not then sufficiently lvanced to enable me to advise definitely which them would be the better one. I formed such a gh opinion of the Government Malaria Depart- ent that I should like to see the whole anti-malaria ork in Ceylon placed under it, if possible, for the ke both of economy and of unity of control cheme A). Failing this, the second alternative cheme B) should be adopted—and I can see no ird course available.

Both alternatives will be, and must be, a source expense. All malaria-control, and, indeed, sani- tion in general, is a source of expense. But it is t yet always clearly apprehended that malaria, e other diseases, is also a source of expense—and ually of much greater expense than preventive easures are likely to be. It is useful to consider is subject from a strictly business point of view, ite apart from humanitarian interests. Every se of malaria, both among staffs and among bourers, costs money; and sometimes large sums money have to be wasted under this heading.

Here, for example, is a table prepared by one of the ost capable rubber planters in Ceylon before my rrival (except for the last column). It gives the ctual loss in the tapping of the rubber-trees due to hortage of labour caused chiefly by malaria in ecember and January last in a group of five estates nder him. Estate I is some hundreds of feet up n the hill above the plain; Estate II is lower down nd nearer the plain; and Estates III, IV and V are ght out on the plain away from the slope of the ill.

It will be observed that the cost of the malaria ncreases in the same order. Now I took the spleen- ates on the first four estates before I had seen the anager's table; and these spleen-rates are here ntered in the last column. It will be seen that hey vary remarkably in agreement with the mone- ary loss shown by him. That loss amounted to early £1,000 for the five estates in January alone, nd varied from nil on Estate I on the hill (with a pleen-rate of only 15 per cent.) to a sum of Rs.5,579 n Estate IV on the plain (with a spleen-rate of 76 er cent.). The increase of the spleen-rates (and f the pecuniary losses) in the estates on the plain was due to the greater frequency of the breeding-waters of the dangerous *Anopheles* there than on the slopes of the hill.

I have no doubt that similar figures can be obtained for all the estates in the island; and, besides the waste of productive labour, numerous other expenses are caused by the disease—hospital and other medical expenses, maintenance of families, and so on. My main argument is, therefore, why waste thousands a year in consequence of malaria when a few hundreds a year may suffice to prevent or at least to diminish it? Even if the preventive measures cost as much as the malaria costs (which will probably be very seldom the case), the humanitarian benefit in the saving of sickness and death will still turn the scale in favour of prevention. There is no alternative left—either prevent your malaria or continue to lose thousands a year in consequence of it.

How should the money be raised to pay either for Scheme A or for Scheme B? Evidently by subscription. The planters themselves must agree upon the terms; but the following points may be submitted for their consideration. The Ceylon estates may be classified as follows:—

Group 1.—Estates (chiefly tea-estates) which are above or outside the malaria range and on which only imported cases occur.

Group 2.—Estates within the malaria range, but on which epidemics of malaria occur only occasionally.

Group 3.—Estates whose coolies become infected from adjacent areas such as neighbouring estates, or towns or villages.

Group 4.—Estates whose malaria is due to their own mosquito-breeding areas.

Until complete malaria-surveys of all the estates have been made, it will be difficult to say to which group any one estate belongs, except perhaps those happy plantations of Group 1 which are entirely above the malaria range. On many estates malaria may be absent to-day but may abound to-morrow (Group 2), and then in consequence either of contiguous foci of infection (Group 3) or of their own breeding waters (Group 4). Malaria is a disease which is by no means always fixed to the same localities, but of which wide epidemics may occur (as shown by numerous careful investigations). In

Total...	5074	4059	1015	9489.40	4513	3244	1269	12943.80	

Total crop in December 22896 lb. at 5½ lb. per coolie, 5582 lb. loss at Rs. 1.70 = Rs. 9489.40.

Total crop in January 19874 lb. at 6 lb. per coolie, 7614 lb. loss at Rs. 1.70 = Rs. 12943.80.

such epidemics the estates of Group 1 may be put to considerable expense in consequence of imported cases, and even such estates are therefore distinctly interested in the whole subject. I conclude, therefore, that it would be proper for *all* the estates to join in the malaria subscription; and as many estates (Group 3) suffer from infections contracted in neighbouring houses, villages, and towns, I think that Government may justly be asked to assist either Scheme A, or by adding an adequate sum to Scheme B. If all the estates in Ceylon can be persuaded to subscribe, the total cost to each would be inconsiderable as regards the malariological department itself; but actually malarious estates (Group 4) would still have to bear the cost of dealing with their own breeding waters, unless neighbouring estates or Government can be induced to help—as may often be the case. Pending consultations and decisions on these points, I advise the more progressive estates to raise a " malaria subscription " at once among themselves and to set to work without delay. They are likely to save much of the money they are now spending in consequence of the disease; and other estates are sure to join them as soon as good results become manifest. All the main scientific facts have been demonstrated for many years; and there is no good reason for procrastination.

The Ceylon Public Health Department has already commenced considerable schemes for malaria-reduction at Trincomalee, at Anuradhapura, at Mahara Prison, and elsewhere, chiefly by mosquito-control. Apart from older attempts in this line, a campaign has recently been described in the Supplement to the *Indian Medical Gazette*, March, 1926, page 1, which says: " Mr. R. Senior-White, F.E.S., records the eradication of malaria from a rubber estate in Ceylon with a total population of 357 souls. From 1914 to 1921 malaria cost the estate approximately Rs. 831 per annum in loss of working days, and the population of 357 showed an annual average of 830 admissions to hospital for malaria. The expenditure upon prophylactic quinine was Rs. 352 per annum. In 1919 a survey was carried out, and *Anopheles maculatus* (an Anopheline mosquito) incriminated. Its breeding places were thoroughly dealt with, chiefly by oiling, at a cost of Rs. 195 per annum. The annual average number of deaths from malaria dropped from 13 to 4, with an estimated saving of Rs. 480 per annum on increased number of days' work. The example is a small one, but it is typical of results which can be multiplied almost indefinitely upon a much larger scale." See also a paper by Mr. Senior-White in the *Bulletin of Entomological Research*, January, 1926 (Imperial Bureau of Entomology, 41, Queen's Gate, London, S.W.7), which has just reached me.

In 1902-3, the Suez Canal Company, acting on my advice, entirely cleared its capital town, Ismailia, of mosquitoes, *Stegomyia*, *Culex* and *Anopheles* (and also of its malaria), and a few years later, Dr. E. H. Ross achieved the same result at Port Said. When we passed through the Canal during my recent journeys both to and from Colombo I heard from several residents in those towns that this happy riddance has been maintained by the local sanitary authorities. It is notorious also that several large cities in North and South America (besides the Panama Canal zone) have also been almost entirely freed from the mosquito-plague. The day will come when all well-managed towns and estates in the tropics will get rid of mosquitoes just as they now deal with bugs, lice, and other vermin —not to mention lions and tigers!—and the whole of my advice to Ceylon is to follow these excellent examples as soon as possible.

The other methods for malaria-reduction besides mosquito-control have been tried in Ceylon, but are not very favourably reported upon by Mr. Carter. Coolies and their families can seldom be persuaded to take quinine regularly, except when they have fever; and when I was Consultant in Malaria at the War Office during the war quinine-prophylaxis in Salonika and elsewhere proved to be only a temporary safeguard against malarial fever. Nets and screens, culicifuges, gloves and veils are also impossible for coolies, and are useful only in the absence of proper mosquito-control; and, as I have said, I was not conscious of being bitten in Ceylon, in spite of faulty bed-nets, or often no bed-nets at all. Mr Carter is breeding large numbers of the small fish which eat mosquito larvæ, and he finds them useful in wells. In my opinion, inadequate or unnecessary wells should be filled up altogether as much as possible. There are always great difficulties connected with paddy-fields, which often, though by no means everywhere, breed the dangerous species of mosquitoes: the rice-plots cannot usually be drained away without interfering with private rights and are in different conditions at different seasons, sometimes suitable and sometimes unsuitable for *Anopheles* larvæ. In fact, this point, and the question of borrow-pits, seem to provide the principal problems of *Anopheles*-control in Ceylon. The future is sure to yield improved solutions.

This is not the place for technical details, but mention should be made of " Paris Green," a fine chemical powder, which, when blown on to the surface of a pool, poisons the *Anopheles* larvæ only, as demonstrated in America. A sample given to me by the Colombo Commercial Company was handed over to Mr. Carter for trial; and the number of the *Indian Medical Gazette* already mentioned describes a very encouraging experiment in Bombay with this substance (page 115). The drawback about it is that it does not kill other mosquito larvæ. For a quarter of a century I have urged that search should be made for an *ideal larvicide*, which can be thrown on to pools in the form of small pellets that will float on the surface of the water and destroy all kinds of mosquito larvæ there without injuring crops or cattle—and I hope to recommence the investigation this summer (after previous failures). Recent studies of the relations between larvæ and the hydrogen-ion contents of various waters made by MacGregor, Buxton, and Senior-White (op. cit.) are also very promising—though one suspects that these con-

ditions may affect the food of the larvæ more than the larvæ themselves directly.

Somewhat too much is being made of small differences in the habits of different species of *Anopheles* larvæ. In his selection of waters which require treatment for malaria control, the wise malariologist will look not only on those which breed culpable mosquitoes to-day, but also at those which may do so to-morrow. He will, moreover, try to remember waters which breed mosquitoes that annoy without carrying any infection. He will cast the net of mosquito-control as widely as possible so as to include as many of the insects as he can. The costs may sometimes be a little more, but the results are likely to be far more complete and satisfactory. On the other hand, where the costs are likely to be much more, he will have to think twice over his recommendations: and the conclusion must depend on local conditions.

I was told that the malaria-bearing species of *Anopheles* have not even yet been fully and satisfactorily incriminated in Ceylon by cultivating or finding the malaria-parasites in them. This should be done at an early date. Quite possibly, if not probably, certain local varieties even of known malaria-bearing species of *Anopheles* may be innocent, and vice versa. Strain as well as species is sometimes concerned in the carriage of parasites.

Much annoyance is caused in many estates in Ceylon, as well as in numerous other parts of the world, by minute little black flies commonly called eye flies, which constantly buzz in the eyes and ears, specially in open verandahs during the heat of the day. Very little definite appears to be known about these insects; but from the fact that they abound much more in certain spots than in other places I conjecture that they breed in connection with some kind of plant or tree, or in some other purely local sites. If so, they might be easily diminished or even banished. I suggest, therefore, that the planters might have these flies thoroughly investigated, if possible. They are also supposed to carry inflammation of the eyes, and, in fact, one of my children acquired a most severe attack of conjunctivitis in Bangalore many years ago, probably owing to infection carried by these little creatures.

In conclusion, I hope that malaria-control will shortly become general in Ceylon, as it is now likely to do in parts of the Indian Empire. All the conditions for advance are present there, and only a suitable organization for private estates remains to be established. This, I am sure, will shortly be done.

Current Literature.

THE AMERICAN JOURNAL OF TROPICAL MEDICINE. March, 1926.

Cure of Clonorchiasis by Tartar Emetic (A. C. Reed and H. A. Wyckoff).—The case is described of a Chinese woman, aged 32, who was excluded from landing at San Francisco because of clonorchiasis. Her general history, unimportant; health, good; and physical examination, negative. Slight secondary anæmia. Stools constantly showed the presence of *Clonorchis* and *Trichuris* ova. Six weeks' treatment with neo-arsenobillon and bismuth-potassium tartrate suspended in oil had no action on the *Clonorchis* and *Trichuris* ova in the stools which were constantly present. A course of tartar emetic treatments was begun, using a fresh, clear 1 per cent. solution in doubly distilled water. Intravenous injections of 3 c.c. and 4 c.c. caused very severe local reaction and thrombosis. Intramuscular injections were then tried, consisting of oil containing 1 per cent. novocain and 0·25 grm. tartar emetic per cubic centimetre of oil. This method had to be abandoned on account of intense local reaction and pain. Intravenous use of fresh 1 per cent. tartar emetic in doubly distilled water was again tried; by starting with a smaller quantity, using a fine hypodermic needle and injecting very slowly local reactions were entirely avoided, and the patient was cured five months later.

Amœbic Colitis. Its Treatment by Trans-Duodenal Medication (A. F. R. Andresen).—Each year five or six cases of amœbic colitis are treated at the Long Island College Hospital. Nearly all are of tropical origin, occurring among seamen from foreign ships in the harbour, but an occasional endemic case is seen. The treatment carried out at the hospital has given very encouraging results, and the patient shows great improvement within forty-eight hours. The active amœbæ are protected from destruction by the plugging of the ulcers with debris. This plug can be removed by the trans-duodenal enema. Powdered ipecacuanha, given through the tube, immediately after the ulcers are cleaned out, can get in its effects where most needed. Emetine, given hypodermically, may be a useful adjuvant.

Some Observations on the Tertiary Lesions of Frambœsia Tropica, or Yaws (L. H. Bittner).—The author is convinced that rhinopharyngitis mutilans, keratoma plantare sulcatum, and juxta-articular nodules are all tertiary lesions of frambœsia or yaws. A case is described of each affection. All these conditions are helped by neosalvarsan alone; in the first, the ulcerative processes can be cured; in the second, the painful fissures can be healed and the soreness relieved, while the indurated skin becomes softer; in the third, the nodules are diminished, but do not always disappear. Juxta-articular nodules, if necessary, can always be removed by surgery without recurrence, where neosalvarsan fails to cure.

Experimental Rat-Bite Fever (M. Theiler).—A spirochæte closely resembling the *Spirochæta morsus muris*, was demonstrated in the blood of guinea-pigs and white mice injected with the blood taken from a typical human case of rat-bite fever. White mice and rats are readily infected with the spirochæte. These animals show no symptoms but harbour the organism in the blood for a long time. Guinea-pigs inoculated

with the spirochæte, after an incubation period of six to fifteen days, develop fever, enlargement of the lymph glands, inflammation, and later induration of the external genitals and loss of hair. Rabbits were infected by subcutaneous, intradermal and intratesticular injection of blood containing the spirochætes. About half of the animals used developed no symptoms, but their blood was infective for guinea-pigs for three weeks after inoculation. In the serum of infected rabbits strong spirochæticidal properties are developed.

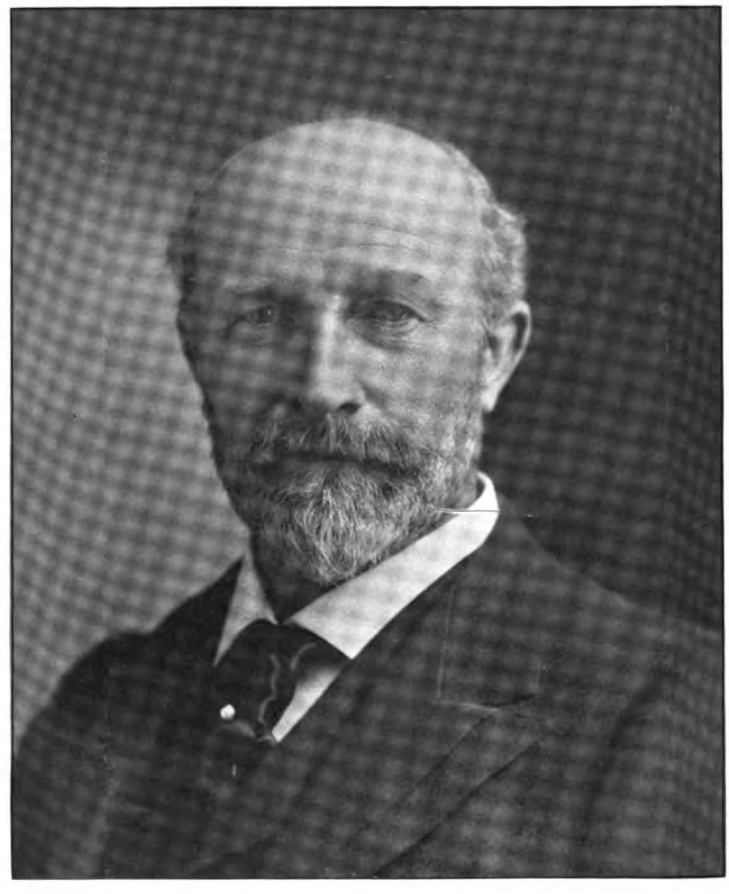
The Significance of Cholesterol in Tropical Hydrocele (H. M. Stenhouse).—The study of this malady has been carried out at the hospitals of St. Croix, one of the Virgin Islands of the United States, where it is very common. *Filaria bancrofti* infects practically the entire populace. Arteriosclerosis, cataract and elephantiasis are frequently observed and at an early age. The cholesterol crystals found in hydrocele are considered by most authors to be a secondary degenerative product, but Stenhouse states that the very density of the crystals in some fluids is of itself a very strong argument against such a theory. Hydrocele develops approximately in one man in eight in St. Croix. It is especially associated with active sexual life; it affects both sexes and becomes gradually more common as we advance through successive age periods. *Filaria bancrofti* takes first place among factors tending to induce hydrocele. The nature of the occupation and hereditary tendencies must be borne in mind. No particular incident has been found to excite the process. Hard work of body may be a partial antidote against hydrocele.

Occurrence of Anopheles vestitipennis in Porto Rico (H. A. Johnson).—This is the first time that larva or adult male of the species has been found in Porto Rico. The recognized home of the species seems to be Central America, and unless the species has been generally overlooked in the West Indies the finding of *A. vestitipennis* so far away from its natural haunts is of particular scientific interest.

The Influence of Obstacles Unconsciously Erected against Anophelines (Housing and Screening) upon the Incidence of Malaria (M. F. Boyd).—In this survey 504 houses were examined, in which there were 298 cases of malaria, or 11·6 per cent. of the population in that area. Blood smears from 175 individuals showed the presence of *Plasmodium vivax* in fifty-six and *P. falciparum* in twelve. None of the dwellings in the survey area could be classified as mosquito-proof, yet it is seen that a house which may not meet the requirements of so-called mosquito proofing can nevertheless afford its occupants a considerable degree of protection. In places where screening existed it had been done as a fly protection, but had served to render the accessibility of anophelines into the dwellings more difficult. The construction of tight, well-screened houses, actually mosquito-proof, should be encouraged.

Reviews.

REPORT TO THE SECRETARY OF STATE FOR THE COLONIES ON THE OUTBREAK OF PLAGUE IN THE GOLD COAST COLONY AND ASHANTI. By Professor Sir William Simpson, C.M.G., M.D., F.R.C.P., D.P.H. Published by the Crown Agents for the Colonies, 1925.



This Report, like all the previous ones presented by Sir William Simpson, is the work of a practised hand. He describes the outbreak of plague which occurred in Seccondee and Coomassie, on the Gold Coast, in 1924, and on the conditions which favoured its prevalence. He points out that until 1924 there had been no serious outbreak of plague on the Gold Coast since 1908, and attributes some of this immunity to the fact that the Gold Coast does not possess any port with a harbour which admits vessels alongside its docks, and thus lessens the danger of importation of the disease by infected rats. The conditions prevailing in Seccondee and Coomassie, which render these towns vulnerable to endemic diseases, are pointed out, together with the measures necessary to prevent further reinforcement from other infected countries. A series of instructive photographs of the conditions encountered complete this excellent report. F. E. T.

THE HEALTH OF THE WORKERS. By Sir Thomas Oliver, M.A., M.D., D.Sc., LL.D., D.C.L., F.R.C.P., Professor of the Principles and Practice of Medicine, University of Durham and College of Medicine, Newcastle-upon-Tyne. London: Faber & Gwyer, Ltd. (The Scientific Press), 1925. Pp. 226. Price 2s. 6d. net.

This small volume constitutes one of the new series of Modern Health Books edited by Professor Fraser Harris, who, in his Introduction to the series states that "every volume has been written, for the benefit of the general public, by a first-rate authority. It is (as it were) a ticket of admission for all and sundry to the marvellous laboratory where science is remaking the modern world." He has certainly succeeded in obtaining a first-rate authority to write on trades as they affect the lives of the workers in Sir Thomas Oliver, who, while avoiding the use of too technical language, has given us an interesting and authoritative, albeit brief, account of the various medical and social problems connected with industrial occupations. F. E. T.

LOCALIZZAZIONE DEI CENTRI CORTICALI PER MOVIMENTI LARINGEI. Luigi Bellucci, Siena, S. Bernardino.

This study of the localization of the cortical centres for laryngeal movements constitutes a handsome monograph of 294 pages, with many charts illustrations, and an extensive bibliography. It is divided into three parts dealing with historical and literary, experimental and anatomico-pathological and clinical data respectively, together with a summary of general considerations and conclusions. It should prove of great value to those interested in this special subject. F. E. T.

SIR JAMES CANTLIE.

K.B.E., M.A., M.B., C.M., LL.D. F R.C.S., D.P.H.

THE JOURNAL OF

Tropical Medicine and Hygiene

JUNE 1, 1926.

Obituary.

JAMES CANTLIE, K.B.E., M.A., M.B., C.M., LL.D.Aberd., F.R.C.S.Eng., D.P.H.Lond., was born in Banffshire, on the Fiddoch, a tributary of the lower Spey, in 1851. In the University of Aberdeen he graduated with honours in Arts, and with honours in Surgery after completing his medical education at Charing Cross Hospital. From this he also took the F.R.C.S., and here he served the various house appointments. A little later we find him Demonstrator of Anatomy, and presently Assistant Surgeon. In these appointments he laid the foundation of his name as a tutor, coaching a succession of candidates who took the highest places in the Examinations for the Public Services. A short visit to German Universities and service in Egypt in the Cholera Outbreak Commission of 1882, as one of "the twelve apostles," were pleasant breaks in his hospital work.

It was in those early days that Cantlie was in a quite casual way introduced to one of the chief interests and occupations of his life—ambulance—by circumstances, almost dramatic, known only to his personal friends. He happened to be asked, through me, to lend a hand in editing the first edition of a *Manual on First Aid to the Injured* being drawn up for the St. John Ambulance Association by my friend, Surgeon Major Peter Shepherd, who was suddenly ordered to the front in Zululand and had to leave the book unfinished. Shepherd fell in Isandhlwana. Cantlie threw himself with all his heart into application of the principles and methods of ambulance to the circumstances and necessities of civil, as adopted in military, life; became associated with the Order of St. John as a Divisional Surgeon; and set out to improve and extend public provisions against accidents and other untoward events by training not only railway servants and factory hands—male and female—but the general population, in the elements of anatomy and of First Aid to the sick and wounded. It was work fated to be of service to his country in war as well as in peace. This was his first step in the direction of public work of this kind.

A second step was momentous; and Cantlie's credit for the issue of it must not be forgotten. He determined to introduce ambulance drill in the Volunteer Medical Service where he was serving as Surgeon to the London Scottish. He made light of criticism, called for volunteers from his students at Charing Cross, drilled them, and—braving authority—had the courage to ask and the good fortune to secure the consent of Lord Wolseley to inspect his little company when he came to distribute the prizes at the Medical School in 1883. His devices to bring together the volunteer students of the different London hospitals by furnishing the Corps with uniform and a band, although fitting material for a comedy, led to success. He next took his men to a field-day. No official protest was made; and in due course the new Corps was recognized. Cantlie had "raised" the Volunteer Medical Staff Corps, destined to become the R.A.M.C.(T.F.), and to be of priceless service in the war, and with much other good work to be rewarded with the rank of Lieutenant-Colonel and a Knighthood.

The year 1887 found him making a complete break in his career as a Surgeon and Teacher in a London hospital, and in his active work, but not his interest, in ambulance. Manson asked me to send him a partner in his practice at Hong Kong, and Cantlie went out. There he spent nine years of busy life. But medical and surgical work was only part of his occupation. He accomplished a third achievement: he found time to lay the foundation of a University. Notwithstanding Manson's hesitation, Cantlie yielded to the desire to teach which always possessed him, and opened a School of Anatomy and Elementary Surgery for young Chinamen, who were to carry from Hong Kong to their ignorant fellow-countrymen in the mainland the learning and methods of the West. The school flourished and developed into the College of Medicine for the Chinese, which is now one part only of the University of Hong Kong with its three Faculties. Its first pupils were less fortunate. It was reported that when they reached their native parts they were seized and executed as rebels. —All but one, who escaped back to Hong Kong and safety, Sun Yat Sen, fated to meet his teacher years later in London and to be rescued by him from imprisonment in the Chinese Embassy and prospective deportation and death, and destined to be President of the Chinese Republic!

On his return to London in 1896 Cantlie readily established himself in practice as a first-hand authority in tropical diseases—one who had studied and treated them in their natural climate. He secured the appointments of Surgeon to the Seamen's Hospital at the Docks and Plague Officer to the L.C.C. He founded and edited this *Journal*; and in it, and generally, took an active part in bringing home to the Government and the City the vital importance of a training in tropical pathology and tropical medicine to our imperial trade and to the nation. In due course we find him Lecturer in the London School of Tropical Medicine and President of the Royal Society of Tropical Medicine.

All these interests did not serve to distract him from ambulance work. On the contrary, he served in it more widely and intensively than before. He attached himself to the two great organizations for ambulance service—St. John and the Red Cross—giving much time to lecturing and practical training in it at different centres; and thenceforward he never forsook ambulance as an interest and a concern conducted side by side with practice in tropical medicine. It was at this stage that he

came to be more and more sought after as the leading teacher of the general population in First Aid, and as widely known by the public as in the profession, rising to the distinctions of Assistant Commissioner of St. John Ambulance Brigade and a Knight of Grace of the Order of St. John of Jerusalem. He was elected a member of the British Red Cross Society, for which he wrote three manuals—on *First Aid*, *Nursing* and *Camp Life and Drill*. The need and value of all this was to be recognized presently; in the war hundreds of pupils passed through his hands, women especially qualifying as V.A.D.'s.

Some of Cantlie's friends have found it difficult to account for his pursuit of interests of this kind—popular lecturing and ambulance drill—in which a rising hospital surgeon and teacher came to interest himself permanently in ambulance and First Aid, outside the ordinary line of professional work. As I knew him from his youth, I recognized that he was naturally an uncommonly acute observer and critic of men and things; and as the range of his observation widened in and after life abroad he was constantly finding something that he considered should be improved, some public want. Hence many of the events of his restless life at Hong Kong and at this time, which brought him credit; hence, also, many notions and schemes which met with criticism and did not mature. With this critical inventive disposition there were united in Cantlie other qualities determining the course that he took. He was impulsive in his projects, making light of difficulties—at any rate he disregarded them, indifferent to criticism, no doubt ambitious. This independent spirit of his, acting on strong convictions, too often led him to consider only the object he had in view, regardless of cost. Other men might have spared neither time nor money for the public good in these circumstances, nor did he; but who but Cantlie would have sacrificed so far professional practice and professional advancement in such a cause as the pursuit of First Aid and ambulance? All the more honour to him! It was for the public good; and through much questioning and discouragement he lived to have his labours recognized by King and Country.

Cantlie's three real triumphs by which he will always be remembered were the training of hundreds of V.A.D.'s in the war, the "raising" of the V.M.S.C.—to develop into the R.A.M.C.(T.F.), and the foundation of the College of Medicine for the Chinese. Of smaller, but still of much account, were his provision of a portable X-ray apparatus for the poor in country places, and his scheme for qualifying in First Aid all youths proceeding to business abroad. Of his other original notions one remembers a proposal to bring fresh air into London from Brighton by means of underground tubes; to abolish the Eton jacket in boys because of the unwise exposure of the renal regions: his suggestion that appendicitis may arise in "piles of the appendix" from congestion of the remote roots of the portal system in the ileo-colic veins; and his views on the degeneration of Londoners and the disappearance of their third generation.

Personally, Cantlie presented a hearty, honest, bright manner, expressive of his independent, confident spirit as we have described it. The most cheerful of companions, he had no match in amusing people of all ages. He would nurse an infant for an hour on end, give it its bottle, and finish the contents himself. Men of his own years he entertained with song and story, mostly in broad Scots, rendered with appropriate gesture. He was "guest of the evening" at medical dinners in all parts of the country. There and on platforms he was in his element, and a real artist in oratory of this kind. He preached the sermon on Hospital Sunday in St. Martin's Church, Trafalgar Square. He addressed a Jewish gathering on Moses and Hygiene, with particular relation to plague. And indeed, quite apart from these casual functions, he had no equal of his time as a lecturer and demonstrator—ready, striking, attractive and always interesting and amusing, noted for many sayings which no pupil could forget. Our readers know that he was equally so in his writing which was his other chief pleasure.

Cantlie's health and strength began to give way many months before the end, which mercifully came without distress of any kind. His four sons, whom he educated with judgment, are left respectively in positions of public importance. His wife, his guide and mainstay, died a few years ago leaving him "a different man."

Cantlie's life, when we survey it at its end, in the same generous, kindly spirit which was his own, is seen to have been a life of service to his country—so distinguished in its aims, in its attainments, and as an example, as to be worthy of permanent record in our national history.

J. Mitchell Bruce.

Syphilitic Alopecia: Its Relation to Neurosyphilis (U. J. Wile and G. H. Belote, *Archives of Dermatology and Syphilology*, April 1926).—Syphilitic alopecia of the essential type has a high associated incidence of meningeal syphilis, as indicated by spinal fluid findings. The absence of the accepted criteria in the spinal fluid cannot, moreover, be accepted as absolute evidence of the absence of such involvement. Microscopic study shows that the essential syphilitic alopecia is not due to any local pathologic disturbance of the scalp, or, more specifically, of the follicular apparatus. It is therefore not a true syphilide. Clinical analogy affords the suggestion that it is due to the action of the endocrines on the nervous system. Symptomatic alopecia representing a smaller group of the entire syndrome is a true syphilide, apparently caused by a perifollicular plasmoma.

Original Communication.

THE INFLUENCE OF AN ACID REACTION ON THE VIRUS OF THE CHICKEN SARCOMA (ROUS) AND ITS IMPORTANCE IN THE EXPERIMENTS OF DR. GYE.

By E. Harde, M.D.

In the last few years numerous articles have appeared on the acid reaction of normal and pathological tissues. This acidity has been found in normal active adult tissues, in all embryonic tissues, in inflammatory reactions, in cultures of tissues *in vitro* where the cells are in a state of division, and also in dead and autolysing cells. The importance of this reaction is probably great, but it is not yet completely elucidated.

At the present time I am studying the influence of acidity on the origin and development of certain neoplasms of chickens and of mammals. In this preliminary note I will give the résumé of certain experiments with the virus of the chicken sarcoma (Rous No. 1).

Rous and his collaborators have established the following facts in their classical studies on this sarcoma. They have shown that this tumour is transmissible by inoculation of a filtrate and that within certain limits there is a definite relation between the size of the dose inoculated and the time of appearance and of the development of the tumour. There exists a minimum dose, the injection of which produces a tumour; a smaller quantity will produce no tumour, even though it contains the virus. It is in effect a subtumoral dose. Multiplying the dose increases the activity of the virus, to a certain extent. Here, also, there exists a limit beyond which further increase of the virus produces no further increase of virulence. Rous has also found that with a tumour of low virulence, injection of small doses or of the filtrate may be followed by a tumour which appears only after the elapse of some weeks, develops slowly for a time, and then regresses. The virus with which I worked is not very virulent. Chickens live five to eight weeks after being inoculated with the grafts.

With these facts so definitely proven, I am able to study the influence that acidity may have on this virus. 1 to 2 grm. of a chicken sarcoma were ground up, mixed with physiological salt solution or Ringer's solution, and filtered through sand and paper pulp. This filtrate was neutral or slightly alkaline. I divided it in two parts, the first was left neutral, the other part was acidified with an acid salt KH_2PO_4 to a pH 5·5. An equal dose of each of these solutions was injected into the pectoral muscles of a chicken, one dose in the right side, the other in the left.

On the side of the acid injection a tumour appeared within twelve days and invaded the entire pectoral muscles, whilst following the control neutral injection there was a small tumour three weeks later, which developed very slowly, and at the death of the chicken was only 2 to 3 centimetres in size.

In this experiment the slow apparition of the tumour, its limited growth produced on the control injection, neutral solution, shows it to be a dose of the virus at its lower limit. The addition of a small quantity of an acid salt is sufficient to activate this minimum tumoral dose so that it acts as a multiple dose. As we have said before, Rous showed that the rapidity of appearance and development of this sarcoma is proportional to the dose or virulence of the virus.

With a multiple dose of the virus the tumour produced by the acidified filtrate has been twice as large as that caused by the control injection in neutral solution. Here, also there is a definite increase of virulence. There is, however, a point at which lowering the pH no longer produces an effect: that is to a very virulent or multiple dose. This is again in accord with Rous's findings, that the action of the virus cannot be increased beyond a certain limit.

In other experiments the quantity of the virus was diminished, until the control neutral injection was not active and the acidified filtrate caused a small tumour, which appeared late and regressed.

Further, I have found that too great an acidity is harmful to the virus. Single control injections of a solution of acid salt alone produced no tumour. The action of repeated injections is now being studied.

Discussion.

The above experiments have clearly shown that the virulence of a filtrate of chicken sarcoma can be changed—increased or diminished by the addition of a variable quantity of an acid salt—the monopotassium phosphate. Since by an appropriate acidification the virulence of the filtrate may be considerably increased, it is of interest to examine Dr. Gye's experiments on the chicken sarcoma.

His work has been reviewed so extensively that I will only give a brief résumé. First, however, I desire to call attention to one fundamental fact. In every experiment in which Gye finds increased virulence, acidity has been added. Whenever he mixes his two factors, one of those factors is always acid, whether it be a "culture" it is acid, or whether it be the superficial layer of a centrifuged liquid, it also is acid. Gye neglects this acidification completely, since all his control injections (which prove but slightly active or non-virulent) are made with the solutions of neutral or alkaline reaction.

Gye considers that two factors are necessary for the production of tumours—one non-specific, which he considers to be almost certainly a virus; the other, the specific adjuvant, which determines the nature of the tumour. The first factor injected alone is not virulent. Gye thinks he has proved that it exists separately in old non-virulent primary cultures and in subcultures of chicken sarcoma, in

cultures of various other tumours and in the non-active washed deposit—obtained after centrifuging a primary culture or an acidified filtrate. The second factor, the specific adjuvant, Gye finds in the chloroformed filtrate of the chicken sarcoma or in the supernatant fluid after centrifuging an acidified filtrate or a primary culture. This factor injected separately is but slightly active or not at all. Gye bases his hypothesis on this separation of the two factors necessary for the formation of a tumour, a separation which he obtains either by the use of the centrifuge or by the use of chloroform and by his so-called "cultures" of the virus of neoplasms.

Let us examine the simplest series. Gye centrifuges a filtrate acidified by the addition of monosodium phosphate. The supernatant fluid is slightly if at all virulent, whilst the deposit is active. He washes the deposit twice with salt solution. The final emulsion in a neutral solution is inactive at a certain dose. He renders it virulent by adding the supernatant fluid, which is acidified by the NaH_2PO_4 (mixing half the dose of each solution when injected separately). It scarcely seems necessary to introduce a specific adjuvant in this experiment when one takes into consideration the work I have just reported. Gye, himself, says the virus is contained in the washed deposit. It seems to be a subtumoral dose in a solution of neutral reaction which is activated not by the addition of a specific adjuvant, but simply by the addition of a solution of an acid salt containing a small quantity of virus. The centrifuge has not completely removed the virus from the supernatant fluid, since frequently Gye finds that when injected alone it causes a small tumour. The other experiments are more complicated. Gye inactivates a filtrate with chloroform (as shown by Rous and his collaborators). He injects:

1. **Two doses of the chloroformed filtrate.**
2. **Two doses of a subculture of the filtrate always inactive—always acid.**
3. **A mixture of one dose of No. 1 and one dose of No. 2.**

The result depends upon the quantity of chloroform used; with a certain dose of chloroform the treated filtrate no longer produces a tumour, but it is activated by the addition of a subculture which is always acid in reaction.

Gye remarks that if he does not use sufficient chloroform the treated filtrate alone may produce a sarcoma, but if he adds too much chloroform, the virus is definitely inactivated, not even the addition of a subculture will activate it. Gye uses for his "cultures" of the virus of neoplasms a special KCl glucose bouillon to which is added rabbit serum, and a large quantity of tissue. His primary cultures of the chicken sarcoma contain 1 to 2 grm. of the tumour to 6 c.c. of fluid incubated anaerobically. In the subcultures he substitutes chick embryo for the chicken sarcoma. Not only has he activated the chloroformed filtrate with subcultures of the chicken sarcoma, but also with cultures of the virus from diverse mammalian tumours. Because of lack of control experiments published, his work has always been open to an entirely different interpretation. The recent experiments of Murphy on this very point have definitely confirmed this opposing view. Gye gives no control work by activating the virus with "cultures" of embryonic tissue alone. Murphy activates a chloroformed filtrate with a "culture" of chick embryo or of mouse placenta, and obtains results which duplicate exactly Gye's work with so-called "cultures" of the virus of neoplasma. Concerning Gye's specific adjuvant in these experiments it is a chloroformed filtrate partially inactivated and rendered virulent by the addition of "cultures." Gye finds that his cultures are very acid. Murphy states that the embryonic tissue or mouse placenta were selected for the control "cultures" because they share with malignant tissue the ability to utilize sugar in their metabolism under anaerobic conditions, and Murphy adds "this seemed important in view of the possibility that the substance activating the chloroform treated filtrate might be a product of metabolism." Murphy does not give the reaction of his "cultures" of placenta or chick embryo, but as the sugar has been utilized the reaction is certainly acid.

Therefore in this series of experiments also the acidity undoubtedly is of importance in the activation of the chloroformed filtrate, but here it is possibly associated with other factors extracted from the embryonic tissue.

Résumé and Conclusions.

An acid reaction is formed in many active tissues, both in the vegetable and animal kingdoms, in normal and in pathological conditions. It is not yet completely understood. Many observations exist which suggest that it plays an important rôle. I will quote but a few facts, which bear on tumour formation.

Erwin Smith discovered that tumours of many species of plants are caused by a bacillus (*Bacillus tumefaciens*). Smith and his collaborators think that the bacillus acts indirectly by the formation of lactic acid. Recently this theory has found support in the experiments of Blumenthal and Meyer. These authors have produced typical tumours on slices of carrots by the use of lactic acid. Experiments on tissues of the animal kingdom are, unfortunately, more complicated. If this reaction stimulates the division of cells, one can attribute to it a considerable importance in the origin of tumours. Neoplasms are always preceded by chronic irritation, causing death of cells and a resultant local acidity. Rhodenburg has developed a theory of the ætiology of tumours partially based on this fact. The question can be studied from other directions, the possibility of changing the reaction of tumour tissue and the effect such a variation might produce. We are at present working on these lines.

In this preliminary report I have been able to

show the influence of an acid reaction on the virulence of the chicken sarcoma and that an appropriate acidity increases the virulence of this virus. Gye has neglected this factor completely in his work, never having controlled it. But each time he was able to show an activation of the virus, acidity was added, whilst the non-active control injections were always in neutral or slightly alkaline solutions.

The recent work of Murphy on control "cultures" of chick embryo and the present experiments on increase of virulence by addition of acidity explain in a simple manner Gye's experiments, an explanation in which neither his two factors nor his supposed "cultures" of the virus of neoplasms is necessary or proven.

Annotations.

Changes in Respiration, in Circulation and in the Coagulation Time of Blood Produced by Sodium Citrate Injections (M. Joannides, *Archives of Internal Medicine*, February 15, 1926).—Studies on man and the dog show that injections of sodium citrate do not usually increase the coagulability of the blood. Intramuscular injections are less dangerous than intravenous injections. A 3 per cent. solution of sodium citrate which is isotonic with blood has been fairly well tolerated by a patient who received from 300 to 450 c.c. intravenously. This practice, however, should be discouraged. Intravenous injections of great concentrations of sodium citrate are dangerous because they cause immediate respiratory and circulatory collapse. Calcium chloride given promptly during the height of toxic symptoms may save the animal from death. But calcium chloride itself is a dangerous drug if injected intravenously in large doses. The toxic symptoms must in some way be associated with changes that concern the coagulation of the blood, because the latter becomes incoagulable under these conditions. As soon as the toxic symptoms subside the coagulation time of the blood becomes normal. Shallow, slow breathing, a rapid and later slow pulse-rate, convulsions, at times salivation and incontinence of urine, with a drop in the systolic pressure and increased coagulation time, mark the presence of toxic effects of sodium citrate. Small repeated hæmorrhages, apparently, have no effect on the coagulation time. On the other hand, when larger amounts of blood are removed they cause increased coagulability of the blood. Citrated blood transfusion under such conditions increases the coagulability of the blood still more. There is no apparent difference in the coagulation time of the arterial and of the venous blood. Injections of 0·2 per cent. sodium citrate solution in 0·75 per cent. sodium chloride solution invariably decrease the coagulation time of the blood and do not cause toxic symptoms if the citrate dose is within the subtoxic limits. Sodium citrate apparently disappears from the blood-stream promptly since the toxic symptoms produced by the salt disappear quite promptly. Sodium citrate used in amounts corresponding to those for blood transfusion is a useful drug. In larger amounts or concentrations it is a dangerous drug.

Intramuscular Absorption of Some Insoluble Bismuth Compounds as Revealed by the Roentgen Ray (H. N. Cole, H. L. Farmer, and H. Miskdjian, *Archives of Dermatology and Syphilology*, February, 1926).—A study of cases in which patients received injections with certain bismuth salts deep into the lumbar muscles gives the following data. Finely divided metallic bismuth was unabsorbed in extremes of 44 to 150 days and a median of 143 days. No case of absorption was observed. Bismuth oleate was unabsorbed in extremes of 12 to 68 days and a median of 26 days. No case of absorption was observed. In two observations, no absorption of oxybenzoic acid compound of bismuth was noted after 40 and 44 days respectively. In only ten of forty-four injections of bismuth salicylate was complete absorption noted in a median of plus 45 days, while the injections were still unabsorbed in thirty-four instances with extremes of 14 and 124 days and a median of 30 days. In twenty-two of twenty-nine injections of potassium bismuth tartrate total absorption was noted in a median of 14 days and extremes of 6 to 27 days, while it was unabsorbed in seven injections in extremes of 14 to 39 days and a median of 24 days. These findings indicate that injections of metallic bismuth are dangerous, and, if persisted in, will lead to cumulative absorption and possibly even to fatal results. The same is probably true, although to a less extent, of bismuth oleate. Bismuth salicylate likewise possesses this objection and its use should be replaced by one of the more soluble bismuth salts—perhaps the potassium bismuth tartrate preparations. These salts, especially if injected intragluteally once a week, are probably not so likely to give rise to cumulative action. However, the patient should be observed

closely, as even this salt is not above criticism, so far as its absorption is concerned. The contention that insoluble bismuth salts must be injected twice a week is open to question, as only a small amount of the salt will be absorbed at the most. Moreover, too frequent deposits may lead to cumulative action, toxic symptoms and even the death of the patient.

Treatment of Neurosyphilis with Tryparsamide (P. A. O'Leary and S. W. Becker, *Medical Journal and Record*, March 3, 1926).—The use of tryparsamide at the Mayo Clinic, extending over a period of three years, in 207 cases, leads to the belief that although its use is still in the experimental phase, tryparsamide is of value in the treatment of the paretic type of parenchymatous neurosyphilis. It does not seem to offer as much encouragement as the treatment of general paresis with malaria, but it is available for those not suited to the risk of the latter treatment. Evidence, based on subjective and serological improvement, justifies the assertion that there is a certain small group of patients with paresis who derive marked benefits from tryparsamide. In seven cases in the whole series there was a complete reversal of the spinal fluid findings to normal, but no associated clinical improvement. The authors were unable to ascertain the clinical and serological criteria by which to determine beforehand the patients with paresis who will improve. The objective visual complications offer a hazard (4·3 per cent.) which could not be prevented by special precautions. The mechanism of this complication has not as yet been described. The use of bismuth intramuscularly in conjunction with tryparsamide seems to offer better therapeutic results than either given alone. The low cost, availability, and small percentage of complications and reactions are among the advantages of the drug. The continued clinical use of tryparsamide may eventually determine the niche in the armamentarium of neurosyphilitic treatment in which it is to give the most encouraging results, but until that time its use is warranted as a valuable adjunct in the treatment of the patient early in the course of general paresis.

Dengue. Its History, Epidemiology, Mechanism of Transmission, Ætiology, Clinical Manifestations, Immunity and Prevention (J. F. Siler, M. W. Hall and A. P. Hitchens, *The Philippine Journal of Science*, January-February, 1926).—This paper is the only one in the volume of 304 pages. The summary is as follows: Dengue and yellow fever are transmitted by the same species of mosquito (*Ædes ægypti*) and the mechanism of transmission for both diseases is strikingly similar. Epidemics of both dengue and yellow fever are therefore subject to the same control measures. The control of epidemics of dengue usually is accomplished by a material reduction in the mosquito population of the community. The mechanism of transmission briefly is as follows: The dengue patient infects mosquitoes during the first three days of illness; the infected mosquito is able to transmit the virus eleven days after its infection; infected mosquitoes remain infective throughout life; hereditary transmission of the virus does not occur. Epidemics of dengue can occur only when there are simultaneously present cases of dengue fever, large numbers of *A. ægypti*, and large numbers of non-immune individuals.

A. ægypti control campaigns must be based upon a consideration of its life habits; it is one of the most highly domesticated of mosquitoes; it apparently does not hibernate; it disappears when the atmospheric temperature falls appreciably below 59° F. and remains there for any great length of time; it prefers to take blood from man; it is essentially a day-biter, but may take blood at night; its average length of life, under natural conditions, is probably not more than six weeks; it breeds by preference inside human habitations and on the premises thereof; it practically always deposits its eggs in collections of clear water; its eggs, being very resistant to an unfavourable environment, retain their vitality after storage in a dry place for several months; the eggs hatch normally in three days and the adult (free-flying stage) emerges ordinarily from eight to fifteen days later.

Dengue preventive measures are based on two lines of attack, namely, co-operative effort on the part of individuals, both sick and well, and organized mosquito control campaigns on the part of the public health authorities. Co-operative effort on the part of individuals should include the following factors: Patients should protect themselves from the bite of *A. ægypti* mosquitoes during the first three days of their illness; mosquito nets should be used at night and during afternoon siestas; non-immune persons should avoid homes in which secondary cases of dengue occur; householders should destroy adult mosquitoes observed within the house; water should not be permitted to stand in uncovered receptacles in the house or on the premises for a longer period than seven days. Consideration should be given to a number of factors preparatory to the formulation of the plan of campaign. If dengue has been endemic for a long period, many of the natives will have acquired more or less immunity, and epidemics usually are confined to the newly arrived non-immune foreigner from areas where dengue is not endemic. If the rate of flow of the non-immune population is small, extensive outbreaks are not likely to occur, and vice versa. In areas of endemicity maps should be prepared showing the following data: Residential sections of the major part of the foreign non-immune element of population; the parts of the city in which a permanent type of construction for buildings predominates as distinguished from construction of a temporary character. Charts showing daily rainfall, humidity and temperature should be plotted. During certain seasons of the year the rainfall will be so low and

may evaporate so rapidly that it would be impossible for *A. ægypti* mosquitoes to breed out in casual rain-water containers. During such seasons and under such conditions, inspection for breeding places should be concentrated on the other natural breeding places of *A. ægypti*. Temperature conditions influence the seasonal distribution of dengue, and in localities in which the temperature falls below 50° F. and remains there for a considerable period of time, epidemics of dengue will necessarily end with the advent of cold weather.

In carrying out anti-mosquito campaigns the principal line of attack should be eradication of the breeding places (antilarval measures), but this should be supplemented by co-operative efforts on the part of the individual. The active interest and support of a moderate proportion of the population can be secured if adequate publicity of an educational nature is carried out. The area to be covered should be divided into districts and adequate and competently trained personnel assigned to each district as inspectors. Inspection should be made at intervals of not more than seven days, and weekly reports relating to breeding places detected should be submitted and consolidated in order that the effectiveness of the work may be evaluated.

Rectal Injections of Quinine (W. Fletcher, *Bulletins from the Institute for Medical Research, Federated Malay States*, No. 1 of 1924).—In the year 1923 an account was published of the unsatisfactory results which follow rectal injections of quinine, and of the pain and tenesmus which they sometimes cause. These conclusions were greatly at variance with established opinion and, in consequence, the Medical Research Council and the Medical and Sanitary Advisory Committee of the Colonial Office asked that further investigations should be made. First, injections were given to guinea-pigs. These were returned too quickly to allow satisfactory absorption of quinine to take place. Secondly, a series of rectal injections were given, two each day for at least six days, to a couple of groups of men infected with malaria. The first group, consisting of ten patients, received 20 gr. of quinine bihydrochloride, dissolved in 4 oz. salt solution, at each injection. The second group, which comprised six men, received the same quantity of quinine, but it was dissolved in 8 oz. of saline, instead of 4 oz. In the first group, out of seventy-one injections, sixty-two were returned during the first twenty minutes; none was retained permanently; the average time of retention was thirteen minutes. Quinine was found in the urine after only thirty-six out of 132 injections. In the second group, out of thirty-two injections in which the time was noted, three were retained permanently and the average time of retention, for the remaining twenty-nine was seventeen minutes. Twenty-five were returned within twenty minutes. Quinine was found in the urine after thirty-three out of fifty-seven injections. In many of the cases where quinine was present the amount was very small. When 10 gr. twice a day were given by mouth instead of 20 gr. by the rectum, abundant quinine appeared in the urine. In eleven out of the sixteen cases of malaria in the two groups, 40 gr. of quinine bihydrochloride, given daily per rectum, failed to get rid of asexual parasites within a week. Quinine was then administered to these patients by the mouth, with the result that the parasites quickly disappeared. Rectal injections, containing 2½ gr. and 5 gr. to the ounce, were given to a healthy European but he was unable to retain them for more than ten or fifteen minutes, and the absorption from 60 gr. injected into the rectum appeared to be inferior to the absorption from 2½ gr. given by the mouth. The presence of mucous and membranous shreds, passed by patients undergoing treatment with rectal injections of quinine, demonstrates the irritating action of the drug upon the mucous membrane.

Medical Research in China (E. V. Cowdry, *Science*, October 23, 1925).—Attention is called to the noteworthy feature of the contributions, namely, to the co-operation of foreigners and Chinese. It is naturally chiefly a matter of the teacher working side by side with his Chinese student, although some of the more mature Chinese have already made important discoveries alone. It is hoped that in the years to come the tendency to work together, once happily initiated, will continue. It is confidently believed that when experienced and fully trained Chinese and foreigners will join hands in united effort, fortified as they are by their peculiar heritages and intellectual endowments, a new force will be brought into medicine, and that mysteries will give way which have long baffled the best minds of England, France and Germany, indeed, of all the nations of the west labouring alone. That this new combination should act in one of the greatest of oriental cities, in an environment rich in intellectual and artistic achievement and altogether different in character from that which has fostered the advancement of science along certain lines in the west, is another factor which may be productive of surprising results. The future is full of promise, and there is a chance that the Pekin Union Medical College may contribute, as few other institutions are privileged to do, towards the purpose of the Rockefeller Foundation, namely, "the welfare of mankind throughout the world."

Important Features in the Correct Diagnosis of Dysentery in India (J. A. Manifold, *Journal Royal Army Medical Corps*, February, 1926).—The summary of this interesting article is as follows: In Poona, at least among the military population, bacillary dysentery, usually mild, is much more prevalent than amœbic dysentery. This finding

agrees with the finding of Majors Acton and Knowles, and of Major Cunningham, working in other parts of India. The paucity of bacillary cases recorded in the past is due to (*a*) many bacillary cases having been erroneously diagnosed as amœbic in origin. (*b*) Owing to the mildness of the symptoms of the cases, many having been diagnosed diarrhœa, colitis, &c., in lieu of dysentery.

The cause of these errors has been: (*a*) Lack of recognition of the character and importance of the cellular exudate in bacillary dysentery, and the diagnosis of macrophage endothelial cells containing red blood-corpuscles as *E. histolytica*. (*b*) Lack of co-operation between medical officers in charge of cases and laboratories.

The result of these errors is that medical officers have believed most intestinal disorders to be due to infection by *E. histolytica*, and emetine has thus become an unnecessarily prominent feature in the treatment of these disorders.

The remedy can be obtained: (*a*) By increased co-operation between clinicians and the laboratory. (*b*) By the D.A.D.P. instructing medical officers in the preliminary precautions that are necessary to establish a correct diagnosis. (*c*) By laboratory workers without recent training (and even those with training only after a large experience) not accepting a cell as *E. histolytica* in the blood and mucus from a case of *acute dysentery* unless it contains red cells and is actively motile. (If non-motile, a worker with large experience might make a specific diagnosis after employing Heidenhain's iron hæmatoxylin stain, not otherwise.) (*d*) By the D.A.D.P. accepting no diagnosis from a subordinate until he has confirmed it himself.

Studies and Observations on Soil Infestation with Hookworm in Southern Alabama from October, 1923, to September, 1924 (D. L. Augustine, *American Journal of Hygiene*, March, 1926).—A study was made in Covington County, South Alabama, on the development and length of life of hookworm larvæ throughout the year 1923-1924. Soils from polluted areas around rural schools and private homes were not found to contain infective hookworm larvæ later than December 27. No infective hookworm larvæ were isolated from polluted soils from December 27 to March 3. Reinfestation was encountered after March 3, which increased in intensity with the approach of the summer months. The failure of hookworm ova to develop into the infective stage during the winter months in Alabama may be attributed to the frequent frosts and low temperatures of that season. Frequent dry periods during the spring were found to check hookworm development entirely. Soil infestation about the houses was usually found to be of less than one month's duration during the summer months. The early death of hookworm larvæ may be ascribed to the rapid drying of the sandy soils. A series of field experiments demonstrate: (*a*) That only a few hookworm ova develop embryos during the winter months. (*b*) That hookworm ova may appear viable for longer than one month at the winter temperature of South Alabama, but fail to develop into the infective stage, when placed under favourable conditions. (*c*) That a high mortality occurs among young hookworm larvæ, even under favourable conditions in nature.

Hookworm Infestation and Re-infestation in Ceylon. A Study of High Incidence with a Moderate Degree of Infestation (J. F. Docherty, *American Journal of Hygiene*, March, 1926).—Over 20,000 egg counts have been made in Ceylon by the dilution egg-counting method, most of which are analysed in this report. Accepting the villagers' statements as to treatments received, the percentage of the original infestation retained at the close of a campaign, after one and two treatments with carbon tetrachloride or a carbon tetrachloride-chenopodium mixture, was 40·5 per cent. and 24·8 per cent. respectively. Infestation in the Western Province is dependent on the age of the individual. The value of mass treatment, at frequent intervals, receives strong support, for Ceylon, as evidenced by the amount of hookworm infestation that rapidly returns after intensive campaigns. The amount of infestation is much greater in estates than in neighbouring villages with the same altitude and rainfall. Average egg count data per person give evidence of a greater amount of infestation in regions of highest rainfall when altitudes are approximately alike. They also give evidence of a decreased amount of infestation with an increase in altitude in districts with the same rainfall.

The Relation of the Type of Soils of Alabama to the Distribution of Hookworm Disease (D. L. Augustine and W. G. Smillie, *American Journal of Hygiene*, March, 1926).—Laboratory experiments and infection surveys were made to determine the relation of types of soils of Alabama to the distribution of hookworm disease. An account is given of the probable introduction of hookworm into Alabama with a review of its distribution at the time of the original hookworm surveys made by the Rockefeller Sanitary Commission. An intensive study was made on the different types of soils of Alabama to determine their effectiveness in producing mature hookworm larvæ. Hookworm cultures in the sandy soils were found to give quite uniform yields of mature hookworm larvæ. It appears that the sandy soils of Alabama have an average value of about 43 per cent. Hookworm cultures in the clay soils gave varying yields of mature hookworm larvæ, from 0·006 to 12 per cent. Below 6, yields of different percentages were equally frequent. Their average value was about 5 per cent. The degree of efficiency of soils, tested as media for hookworm cultures, was found to be directly related to their textures, viz., a physical

property. Hookworm surveys on children from different parts of Alabama showed that the incidence of infestation is greatest in the two sandy provinces, the Upper and Lower Coastal Plains, and that hookworm disease is largely limited to the Lower Coastal Plain. The greater severity of hookworm infestations in the Lower Coastal Plain is attributed to the wide extent of that province and its geographic position in relation to the soil provinces of finer textured soils. Light infestations were constantly encountered among children who had lived all or nearly all their lives in soil provinces in which fine, heavy clay soils predominate, but in no instance did these children have heavy infestations. It is recommended that health officers in the hookworm belt determine, by culture methods, whether the soil predominating in their communities or general districts is favourable or unfavourable for hookworm development.

A New Application for Varicose Ulcers (R. H. Davis, M.D., *Archives of Dermatology and Syphilology*, April, 1926). The fifteen cases reported illustrate results in most patients who were faithful in attendance over a long enough period to give the treatment a fair trial. The whole series numbered fifty-five, but some of these patients disappeared from observation before permanent improvement could be expected. The cases were all ambulatory, with one exception, and many of them of long standing. The application consists of boracic acid, 63 grm., potassium hydroxide (stick), 28 grm., water 200 c.c. A complete failure to respond to the treatment was unusual but did occur. It appears to be best to begin the treatment by using the solution one-half strength, increasing tentatively to full strength if the pain is not too great. Some of the chronic indolent cases did not respond until full strength was used, but the majority of the patients did well with a less concentration. If possible, the application should be tri-weekly at least; however, in clinic work this is often impossible. An elastic webbing bandage for severe varicosities was used during the day in a few instances. The authors have used this treatment for two and a half years on all varicose and traumatic ulcers, and have always had encouraging results.

The Use of Mercurochrome-220 Soluble in the Treatment of Infectious Diseases of the Skin (H. H. Young, J. H. Hill, and W. L. Deeny, *Archives of Dermatology and Syphilology*, April, 1926).—In this article the authors present the results obtained by the use of mercurochrome, intravenously, in the treatment of a large number of cases of skin infections. Twenty-four patients with erysipelas, twenty of whom were cured or greatly improved; eleven patients with furuncles and carbuncles, of which ten were cured and one greatly improved; four cases of chancroidal ulcerations, all of which healed rapidly; thirty-six patients with cellulitis and abscesses, of whom twenty-one recovered promptly with no other treatment, and nine of whom showed marked improvement and recovery after mercurochrome therapy, other treatment being also given, making a total of thirty cases, or 83·3 per cent., cured or greatly improved; two patients with gas gangrene, in both of whom the infection was eliminated; one patient with diabetic gangrene, in whom an accompanying infection was checked; three patients with pemphigus, all of whom showed marked improvement, two of them so far without relapse, one with relapse; four patients with psoriasis, two of whom are apparently cured, one markedly improved, and one improved, but with a relapse; one patient with eczema, temporarily improved; one patient with syphilis with exterior skin lesions, in whom the lesions were healed; forty-four patients with leprosy, twenty-eight of whom were improved and with remarkable disappearance of the skin ulcers. The facts given are sufficient to demonstrate that in mercurochrome, administered intravenously, a drug of great value in the treatment of infections of the skin with various streptococci, staphylococci, bacilli, and probably also *B. welchii*, is at hand. Other types of infection, the organism being unknown, may also be favourably and rapidly influenced by treatment. This series of cases is presented with the hope that it may stimulate sufficient interest among dermatologists to bring about a thorough trial of the drug in dermatology, a field which offers every prospect of splendid success.

Intestinal Intolerance for Carbohydrate Associated with Overgrowth of the Gas Bacillus (Bacillus Welchii) (A. I. Kendall, *Journal of the American Medical Association*, March 13, 1926).—The syndrome here described is one rather commonly encountered among persons of middle age. There is no outstanding qualitative symptom. The patients are, as Robert Koch once said in another connection, "enjoying a state of rude health," neither conspicuously ill nor fully well. The ætiology, which seems to be associated with intestinal intolerance for carbohydrates (especially the small intestine) is not at all clear. Gas bacilli, less commonly members of the mucosus group of bacilli of the starch fermenting type, are found in unusual numbers in a great majority of cases. It is not predicated, however, that these organisms are necessarily the primary incitants of the disorder. The hypothesis is advanced, and there seems to be some basis in fact, that one important factor in the overgrowth and probable upward extension of the gas bacillus is a decrease in the number of normal lactic acid bacteria in the small intestine. Adding preformed lactic acid to the intestinal contents by frequent administration of well-soured milk tends to correct this deficit. Whatever the cause may finally prove, a regimen containing low carbohydrate, considerable protein and some fats,

together with liberal and frequent administration of well-soured milk, has proved to be of very definite —almost specific—value in re-establishing normal intestinal conditions.

A Case of Sickle Cell Anæmia in the Sudan (R. G. Archibald, *Trans. of the Royal Society of Tropical Medicine and Hygiene*, *January* 21, 1926).—A case of anæmia associated with marked debility, pyrexia, slight jaundice, œdema of the feet, enlargement of the liver and lymphatic glands, occurring in a native of the Sudan, was observed. Blood examination showed a diminution of the red blood-cells, leucocytosis, low hæmaglobin percentage, colour index of 0·9 erythroblasts and phagocytosis of red blood-cells. The most striking feature in fresh and stained preparations of the blood was the large number of elongated and sickle-shaped erythrocytes, averaging nearly 50 per cent. Hanging drop preparations of fresh blood suitably sealed and kept at room temperature (31° C.) showed, after twenty-four hours, nearly 100 per cent. of sickle cells. The sickling is apparently due to some inherent property of the cell, independent of any substance in the serum. The blood-picture is identical with that of sickle cell anæmia, a specific entity investigated by American writers. Clinical characters of the cases corresponded to those of sickle cell anæmia, differing only in the absence of any skin lesion. The ætiology is obscure, cultural tests and animal inoculations yielding negative results.

Treatment of Hookworm Disease in Pregnant Women with Carbon Tetrachloride (J. V. Insfran, *Journal of the American Medical Association*, March 13, 1926).—Pregnancy need no longer be considered a contraindication to anthelmintic medication in areas where *Necator americanus* is the offending agent and carbon tetrachloride the anthelmintic used. The use of a mixture of oil of chenopodium and carbon tetrachloride in areas where *Ankylostoma duodenale* predominates may be possible. The pregnant woman reacts favourably almost immediately to anthelmintic medication.

Hexylresorcinol in Infection of the Urinary Tract. Results in Sixty-three Cases (D. A. Brown, *Journal of the American Medical Association*, March 6, 1926).—Since adopting this technic, no case of gastrectomy has been encountered, even though the maximum specimen has been 23·5 cm. long, in which the stump of the stomach could not be united to the stump of the duodenum by this modified Billroth I operation. If, however, this is impossible, it is believed that the Hofmeister operation, a modified form of the Billroth II, would be the operation of choice. Instead of the stump of the stomach being sutured and an independent posterior gastro-enterostomy being done as in the original Billroth II operation, the upper portion of the stump of the stomach is closed with sutures and the lower third is anastomosed to the jejunum. This is simpler than the original Billroth II, and it seems to be quite as efficacious. It must be recalled that the absence of peristalsis in the left third of the stomach does not necessitate the performance of an anastomosis in any particular axis, because here the contractions are tonic and gravity really helps, whereas in a region of the stomach with active peristaltic waves the anastomosis should be made as far as possible along the lesser curvature.

Gastric Secretion in Experimental Beriberi in the Dog (M. B. Farnum, *Archives of Internal Medicine*, February 15, 1926).— Feeding a beriberi-producing diet to a dog gradually decreases the total volume as well as the free and the total acidity of gastric secretion. The gastric secretory mechanism in beriberi is not only less responsive to the partaking of food, but it is also appreciably more refractive towards histamine hydrochloride injection. The gastric response after gastrin injection is modified only slightly, if at all. The harmful effect of alkali in the autoclaving process is not due to racemization of the proteins, but to destruction of the antineuritic vitamin. The antineuritic vitamin is not a gastric secretagogue.

Studies of Trichomonas buccalis (M. J. Hogue, *American Journal of Tropical Medicine*, January, 1926).—*Trichomonas buccalis* has been found only in the mouths of persons suffering from pyorrhœa, acute gingivitis, or abscessed teeth. It has been found in upper and lower jaws in negroes and in white persons. Four of nine cases were examined for *Trichomonas hominis* and found negative. It has been cultured for over seven months with more than 112 transfers. It grows well in acid and in alkaline media. The thermal death point is 45 degrees for five minutes. It contains neutral red granules when stained with neutral red. It has the power of reducing janus green B. to diethylsafranin. It has round and slightly oval mitochondria. Neosalvarsan is not specific for *T. buccalis*.

Blood Cholesterol Findings in Syphilis and in Other Skin Diseases. An Accurate Technic for Extracting Blood Cholesterol (I. Rosen and F. Krasnow, *Archives of Dermatology and Syphilology*, April, 1926).—The blood cholesterol was low in 100 per cent. of the patients with untreated primary syphilis, 50 per cent. of the untreated secondary cases, and in 25 per cent. of the untreated tertiary cases. After treatment all our primary cases showed a rise in the cholesterol content to normal or above normal, whereas some of the secondary and tertiary cases remained a low

value. The blood cholesterol content in two infants with active manifestations of syphilis was low. The blood cholesterol content in 82 per cent. of the treated patients who had congenital syphilis was normal. There seems to be no direct connection, at least so far as these studies are concerned, between the cholesterol content of the blood and the results of the Wassermann reaction. The cholesterol content of the blood was high in psoriasis and dermatitis venenata, and normal in acne vulgaris, dermatophytosis and dermatitis seborrhœica.

Typhoid Fever in Cochin China (P. Lalung-Bonnaire and R. Pons, *Arch. des Instituts Pasteur d'Indochine*, Oct., 1925).—Typhoid fever was identified for the first time in Cochin China in 1861 and it is still widely spread throughout the country. No race is exempt from the malady, both natives and Europeans are equally affected. The atypical form is more frequently met with in natives than in Europeans.

Notes on the Ætiology of Eczema (F. C. Combes, *Medical Journal and Record*).—It has been proved that external irritation alone is not a sufficient cause for eczema. In those cases in which external irritation is the sole apparent cause, a parasite is probably present, and it can be assumed that a non-eczematous lesion is being dealt with. The most reasonable cause of the disease lies in a lack of balance in the autonomic nervous system, associated usually with an external exciting factor. The internal treatment of the disease should be along lines to restore this balance to normal, rather than by measures directed towards the collection of the various manifestations of vagotonia and sympatheticotonia.

A Contribution to the Study of Onchocerca volvulus Leuckart, with some Observations on its Prevalence in Nigeria (N. A. Dyce-Sharp, *Trans. of Royal Society of Tropical Medicine*, January 21, 1926).—The author's investigations were carried out at Kaduna, Nigeria, where onchocerciasis is not rarely met with; it is far more common than has hitherto been described, but so far has never been observed in Europeans. Onchocerca carriers are usually healthy individuals who do not always exhibit obvious tumours or skin affections. The embryo is more often found in the skin than in definite tumours. The larvæ of *O. volvulus* occur with great frequency in hydrocele fluid in Nigeria, and while possibly innocuous, they may well stand in some causal relationship to this condition as well as to elephantiasis. *Agamofilaria streptocerca* Macfie and Corson, 1922, is not found at Kaduna among natives drawn from all over the country. This organism, moreover, is easily distinguishable from the embryos of *O. volvulus*, with which, on the Gold Coast, it is so often associated.

Reviews.

A Manual of Bacteriology, Clinical and Applied. By R. Tanner Hewlett, M.D., F.R.C.P., D.P.H., Emeritus Professor of Bacteriology in the University of London. Eighth edition. Pp. 645. With 38 plates and 63 figures in the text. London: J. & A. Churchill. 1926.

Hewlett's Bacteriology, which has so long been considered the foremost English manual on this subject, now appears in the eighth edition. Being so well and so widely known, it suffices to indicate the changes which the new edition incorporates. Partly by the use of new type, but chiefly by rigorous revision and the omission of old matter which has served its purpose, the author has actually succeeded in cutting down the size of the book by about 160 pages, and this notwithstanding the inclusion of much new work. On this feat alone Professor Hewlett is to be congratulated, and has doubtless earned the gratitude of the overburdened student. In addition to many revisions and extensions throughout the book, with the addition of new methods in many sections, the chief new work includes a chapter on the neurotropic viruses, including herpes, the Oskov technique of single cell culture, the bacteriophage, tularæmia, *Bacterium pneumosintes*, Rámon's flocculation test in the standardization of diphtheria antitoxin, the Sigma reaction, Kahn's precipitation test for syphilis, the Dick test for scarlet fever, and Gye and Barnard's recent work on malignant disease. This enumeration clearly indicates how thoroughly up to date this edition has been brought, so that it cannot fail to maintain and may even enhance the high reputation which this manual has always enjoyed. F. E. T.

Yatren 105 in the Treatment of Amœbic Dysentery. By Prof. Dr. R. Ruge. The Behring Works Publication Department, Marburg-Lagn.

This monograph contains an interesting illustrated account of amœbic dysentery in all its aspects with special reference to the use of Yatren 105, with which better results are claimed than from the use of emetin without the dangers attendant on the use of the latter. In an appendix it is also stated that in bacillary dysentery and in *Trichomonas*, *Lamblia* and *Balantidium* infections good recults are obtained by the use of this medicament. F. E. T.

The Engineer and the Prevention of Malaria. By H. Home, M.Inst.C.E. Pp. 176. Price 13s. 6d. net. London: Chapman & Hall. 1926.

This volume appeals both to the engineer and to the medical practitioner working in tropical regions. General engineering literature contains very few references to the problems of the transmission and prevention of malaria. The author has here gathered together a sufficiency of public health, entomology and parasitology to give the engineer a general view of the modern field of operations, gained from experience on the Central American coast, the

West Indies, the West Coast of Africa, Egypt and Syria. The engineer is thus placed in a position to criticize the design of engineering works from the antimalarial viewpoint and to design the necessary ancillary works required by malarial conditions. The medical officer, again, will learn many engineering details in connection with houses and quarters, drainage, oiling, mosquito netting, and so on. The book is profusely illustrated and well got up.

F. E. T.

A Text-Book of Midwifery for Medical Schools and Colleges in India. By Kedarnath Das, C.I.E., M.D., Professor of Midwifery and Gynæcology, Carmichael Medical College, Calcutta. Second edition. Pp. 495, with 281 illustrations. Calcutta and Simla: Thacker, Spink & Co. 1926.

We consider that the students in the medical schools and colleges in India should consider themselves fortunate in having this book specially written for them, and it should prove a great success. It contains a large number of illustrations, chiefly from classical sources, and all duly acknowledged, and constitutes a concise, practical, reliable and thoroughly up-to-date guide to the theory and practice of modern midwifery. F. E. T.

The House-Fly: Its Life-History, Importance as a Disease Carrier, and Practical Measures for its Suppression. By Major E. E. Austin, D.S.O., Deputy Keeper, Department of Entomology, British Museum (Natural History). Economic Series, No. 1a. Pp. 61. Price 1s. London: Printed by Order of the Trustees of the British Museum, 1926.

This is the second edition of a pamphlet published in 1920 under the slightly different title, "The House-Fly: Its Life-History and Practical Measures for its Suppression." This new edition has been thoroughly revised and expanded by the addition of new matter dealing respectively with insect enemies of the house-fly, the insect's connection with animal disease, and bionomics and control. This excellent pamphlet, with its instructive illustrations, contains all that is needful for the medical student and practitioner to know. F. E. T.

A Synopsis of the Families and Genera of Nematoda. By H. A. Bayliss, M.A., D.Sc., British Museum (Natural History), and H. Daubney, M.Sc., M.R.C.V.S., Veterinary Research Laboratory, Kabete, Kenya Colony. London: Printed by Order of the Trustees of the British Museum. Pp. 277. Price 10s. 6d. 1926.

This monograph of Dr. Bayliss and Captain Daubney is not merely a synopsis, but a comprehensive account embracing the nematoda as a whole and containing diagnoses either of genera, or of families or higher groups to which the worker can turn confidently for guidance and assistance in the determination of specimens. The authors consider that the prevailing custom of separating the nematodes into free-living and parasitic groups leads to an unnatural scheme of classification, since all degrees of parasitism, permanent and temporary, are found among them, and any such arbitrary division must be made in total disregard of obvious morphological similarities. The literature is also dealt with up to 1923, the more important sources of information only being given, and no attempt has been made to compile a complete bibliography. Workers in helminthology have long felt the need of just such a volume as the present, and they can turn to this one with the utmost confidence. F. E. T.

Notices.

BUSINESS AND GENERAL.

1.—The address of The Journal of Tropical Medicine and Hygiene is Messrs. Bale, Sons and Danielsson, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to The Journal of Tropical Medicine and Hygiene exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All literary communications should be addressed to the Editors.

4.—All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of The Journal of Tropical Medicine and Hygiene. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is Thirty Shillings per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to The Journal of Tropical Medicine and Hygiene should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

Reprints.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

Original Communications.

NOTES ON THE ANALYSIS OF SPRUE STOOLS.

By H. B. Newham, C.M.G., M.D., M.R.C.P.

Department of Tropical Pathology, London School of Hygiene and Tropical Medicine.

The figures quoted below are derived from a study of eleven cases of sprue which have been under treatment and observation during the past six months in the Hospital for Tropical Diseases connected with the London School of Hygiene and Tropical Medicine.

All the cases studied were typical examples of the disease with well marked symptoms and in a fairly acute stage of the disease on admission. Through the kindness of the physicians of the hospital I have been enabled to make use of their cases for the purposes of this investigation and I desire to record my grateful thanks to Drs. Low, Manson-Bahr and Sir Leonard Rogers for their courtesy and co-operation.

Fat Content.

Chemical analysis of sprue stools, more particularly with regard to the fat content, have been undertaken by various workers. Amongst these several German workers have devoted a good deal of attention to the subject, but from British scientists few definite figures are available.

Cammidge [1] has given figures in thirteen cases of the disease which he has investigated, and Mackie and Malandkar [2] working in Bombay supply details of eighteen cases investigated by them.

The results in both cases show a marked increase in the total fat of the fæces and a definite increase in the proportions of combined fatty acids (soaps) as compared with the normal.

As far as one can judge these results are based on the examination of more or less casual stools, doubtless quite typical specimens, but no mention is made as to the stage of the disease at the time of collection or whether they were twenty-four-hour specimens. With a view to ascertaining whether analyses conducted at definite intervals on typical cases of sprue would afford any evidence as to improvement or otherwise in the general condition of the patient as regards the disease I have carried out weekly analyses on a series of six cases. All of these cases were quite typical and in a fairly acute stage of the disease on admission. All improved enormously, as a result of treatment, with loss of diarrhœa, increase of weight, loss of anæmia and the passage of formed stools.

In all instances Cammidge's method of analysis was followed. Of these six cases four were submitted to weekly analyses over a period of five weeks each whilst one was analysed for seven consecutive weeks and one for eight.

A table is appended showing the average figures for the various constituents obtained in these six cases.

Table I.

Case	Times examined	Total fat per cent.	Combined fatty acid per cent.	Neutral fat per cent.	Free fatty acid per cent.
		43·7	27·3	7·45	9·0
1	8	(50·0—38·0)	(35·6—22·0)	(13·82—1·24)	(14·76— 7·15)
		56·1	35·1	12·26	8·78
2	5	(64·8—49·2)	(47·6—25 2)	(23·87—4·8)	(11·2 — 6·13)
		49 0	25·3	11·24	12·4
3	7	(57·2—38·8)	(34·0—14·8)	(25·78—1·9)	(15·33—10·22)
		47·3	20·5	16·77	10·02
4	5	(56·0—40·0)	(42·0— 8·8)	(24·8 —4·8)	(11·25— 9·2)
		56·0	29·4	14·5	12·07
5	5	(66·0—42·0)	(44·0—20·0)	(31·8 —3·4)	(17·4 — 7·2)
		56·1	32·5	9·2	14·31
6	5	(70·8—41·6)	(38·0—26·0)	(18·5 —0·70)	(18·4 —12·27)

It will be seen that generally speaking the averages for the various substances determined are much on a par with those obtained by Cammidge and Mackie and Malandkar in similar cases.

Table II.—Case 4. Weekly Examinations.

Date	Total fat per cent.	Combined fatty acid per cent.	Neutral fat per cent.	Free fatty acid per cent.
December 15, 1925	56 0	42·0	4·8	9·2
,, 23, ,,	56·0	22 0	24·8	9·2
,, 30, ,,	40·8	8·8	20·75	11·25
January 6, 1926	40·0	12·0	17·78	10·22
,, 13, ,,	44 0	18·0	15·75	10·22

As a result of these repeated analyses certain facts emerge. Firstly it would appear (as is seen in the detailed figures for Case 4 here appended) that with the progressive improvement in the patient's condition the only figures that seem to reflect this improvement are the ones for total fat. These appear to show a slow and very gradual improvement, but not to the extent one would be led to expect from the often very marked or even dramatic improvement in the patient's general condition. Moreover, it seems that a very long time must elapse in a case of sprue before the figures for total fat approximate to normal.

In one instance of the disease in which an analysis of the stool was made eight months after all signs of the disease had disappeared, when the patient was, to all intents and purposes, in excellent health and taking ordinary mixed diet, the figure obtained for total fat still showed an appreciable level well above normal, though marked

improvement is to be noticed in the figures for neutral fat and free fatty acid.

TABLE III.—CASE 7.

Date	Total fat per cent.	Combined fatty acid per cent.	Neutral fat per cent.	Free fatty acid per cent.
June 29, 1925	54·5	13·5	29·1	11·9
July 5, ,,	68·4	34·4	14·7	19·3
April 22, 1926	34·0	22·0	5 87	6·13

Secondly, it is seen that the proportions of soaps, neutral fat and fatty acid vary very largely from week to week. This is well seen in the figures given for Case 4 (Table II).

These variations in the proportions of the different fatty constituents of the stools as noted from week to week might appear to be accounted for by some slight changes and increase in the diet and it was decided to investigate a further case by daily examination of the stools.

In this case, which was one showing typical signs of sprue, but in which definite improvement had set in, daily examination of total twenty-four-hour stools over a period of six days was undertaken, the patient meanwhile having no change made in his diet.

The figures obtained in this case are herewith appended and it will be seen that very considerable variations are to be noted more especially in those for neutral fat, which range between 7·82 per cent. and 1·78 per cent.

TABLE IV.—CASE 8.

Date	Total fat per cent.	Combined fatty acid per cent.	Neutral fat per cent.	Free fatty acid per cent.
April 23, 1926...	48·0	33·2	4·58	10·22

,, 28, ,, ...	48·0	36·0	1·78	10·22

CHOLESTEROL CONTENT.

That the function of the liver is somewhat deranged in sprue is well seen from the marked change to be noted in the biliary pigments. In place of the usual urobilin (stercobilin) a predominance of the colourless urobilinogen obtains and it is to this compound that the well-known pallor of the sprue stool is largely due. Moreover, in the early and acute stages of sprue the liver is commonly much reduced in size and it is only after suitable treatment and when manifest improvement in the general condition of the patient is to be observed that the organ gradually returns to its normal size.

Seeing that the biliary function is deranged in this disease it was considered that possibly some light might be thrown on the nature of this derangement by an investigation of the cholesterol output in the fæces, inasmuch as bile contains appreciable amounts of this substance. According to Matthews [3] cholesterol introduced into the gut with the bile is excreted in the fæces in the form of a reduced cholesterol known as stercorin, and further he states that the output of this compound in a normal individual is approximately 0·9 grm. per diem. Careful estimations of the output of this substance in cases of sprue were made using Myer's extraction method with chloroform, with subsequent application of the Liebermann-Burchardt reaction.

In no case of the disease did the output of stercorin at all approach the figure given as normal by Matthews, and a study of the table appended will reveal that, although considerable variations in the quantities are to be noted at different estimations, in all cases the output was far below the normal.

TABLE V.

LEPTOSPIRA: METHODS OF EXAMINATION: NEW HABITAT OF FREE-LIVING FORMS.

By ALFRED C. COLES, M.D., D.Sc., F.R.S.Edin., M.R.C.P.Lond.

Physician to the Royal Victoria Hospital and to the Royal National Sanatorium, Bournemouth.

THE name *Leptospira* (λεπτός, fine + σπεῖρα, coil) has been given to a new genus of spirochætes on account of their fine and minute spirals.

Noguchi [1], 1922, describes the new genus as follows: "It is a delicate filament with tapered ends, so closely and regularly coiled as to resemble a rope. It is actively motile and shows a tendency to bend one or both ends, forming a *C*, *S*, *Z*, or *J* as it rotates in a fluid medium; in penetrating a semi-solid medium its movements are serpentine, swiftly alternating forward, to the side, and backward, the body being flexible at any point and to any angle. No flagellum has been seen under the dark-field microscope, and preparations stained for flagella so far have not given satisfactory results. Preparations showing a single terminal flagellum at one or both ends appear to me unconvincing.

"In preparations stained by Miss Tilden the organisms gave the appearance of numerous peritrichal flagella of several microns in length along the entire length, and it is not improbable, in view of the

characteristic movements, that the organism is provided with some flagella. . . . The leptospira resists the action of 10 per cent. saponin. These characteristics are sufficient, I believe, to enable one to distinguish a leptospira from the multitude of minute forms of treponemata and other spirochætes."

The pathogenic varieties known up to the present time are:—

Leptospira icterohæmorrhagiæ, discovered by Inada and others, 1916, the cause of infective jaundice, or Weil's disease.

L. hebdomadis, discovered by Ido, Ito, and Waji, 1917, causing seven-day fever of Japan.

L. icteroides, Noguchi, 1917, the cause of yellow fever.

Blanchard and Lefrou, 1922, described a leptospira-like organism in the blood of a case of blackwater fever which they called *Spirochæta biliohæmoglobinuriæ*. This finding has not been confirmed by other workers.

Free-living leptospira have also been found which were regarded as harmless.

Wolbach and Binger, 1914, described such organisms, which they called *Spirochæta biflexa*, in the water of a stagnant pond near Boston, U.S.A.

Uhlenhuth and Zuelzer [11], 1922, "demonstrated in the tap water of Berlin a spirochæte morphologically indistinguishable from *Spirochæta icterogenes* (a synonym for *L. icterohæmorrhagiæ*) and gave it the name of *Spirochæta pseudo-icterogenes*, since it was not pathogenic." Hoffmann calls this organism *Leptospira aquatilis*.

Noguchi, 1922, examined samples of water from more or less stagnant ponds, swamps and ditches in the States. He states: " Dark-field examination revealed the presence, usually in small numbers, of leptospira in all of the samples, although in some instances the number was so small that repeated examinations were necessary in order to find one organism. Both fresh and salt water contained organisms indistinguishable from *Leptospira icterohæmorrhagiæ*; occasionally very short and minute (0·2 × 3 to 4 microns) and very heavy and long specimens (14 to 15 microns in length, maximum width 0·4 microns) were encountered. The spirals of the latter type were so tightly set together that the organisms appeared like a series of flat discs held in a row. These extremely small and large varieties are perhaps two different species, both differing from the *icterohæmorrhagiæ* type. In addition to these varieties, leptospira-like forms without any perceptible elementary spirals, apparently smooth-bodied organisms (?) were observed; whether or not they were motile could not be determined. The movements of all the leptospiras found in water were rather sluggish. We have obtained growth of the water leptospira in impure cultures on our regular leptospira medium, though with considerable difficulty. Inoculation of the leptospira water samples into guinea-pigs, white rats, and mice have been repeatedly made, but no infection could be induced in the animals. Injection of cultures likewise proved to be harmless.

I have been working at various species of leptospira during the last nine years, and my experience, having regard especially to the examination and detection of these illusive spirochætes, may not be without interest.

Methods of Examination.

Leptospira, in the case of infectious jaundice, are to be looked for in the blood, kidney and urine, and the free-living forms in water, &c.

The number of spirochætes in the blood is extremely small and their detection remarkably difficult, and in both Weil's disease and yellow fever it is almost impossible to find them beyond the third or fourth day of the disease. In guinea-pigs inoculated with infected material they may sometimes be found comparatively easily.

In cases of infective jaundice our only chance is by examination of the deposit obtained by centrifuging the *urine*.

Inada [2], 1917, states: " The percentage of spirochætes excreted in the urine gradually increases and reaches its maximum on the 15th or 16th up to the 23rd or 24th day of illness. By the 19th or 20th day practically all cases show spirochætes in the urine. After the 25th day the percentage decreases. Twenty-two out of twenty-four patients had ceased to excrete spirochætes after 40 days; one excreted them on the 42nd, another on the 63rd day. The duration of the most abundant excretion covers from three to six days."

In the Kidney of Rats.—I found that leptospira are detected more readily and in greater numbers towards the outer part of the kidney, a short distance under the capsule, and when making an emulsion with saline solution or simply with sterile distilled water, I avoid the tissue towards the hilus of the kidney. I was subsequently interested to see that Schüffner and Keunen [3, 4], 1923, state that leptospira are not evenly distributed in the kidney of naturally infected rats, but are localized in distinct foci. They are not situated within the tissue, as in guinea-pigs experimentally infected, but are to be found collected together in a number of nests in the convoluted tubules, where thick layers of leptospira cover the epithelium.

In water, leptospira are to be found chiefly in the slimy material lining the walls of a vessel, or by centrifuging the water.

These spirochætes may be examined either in the living condition in moist preparations, or in fixed and stained films, and the examination may be concerned mainly with detecting them, or with a view to the critical examination of their minute structure.

Dark-ground Illumination.

As the leptospira are invisible in the living condition by ordinary transmitted light, it is necessary to adopt some method of dark-ground illumination.

In making wet preparations or dry films it is absolutely essential to have the film as thin as possible. Failure in detecting these very minute spirochætes in living preparations is almost invariably due to

having too thick a layer, as the leptospira are so minute and delicate they either disappear in the depths, or are seen as minute oscillating bright spots of light, probably the ends of vertically lying spirochætes. The same remark applies also to stained films. Next to this, good and clean cover-glasses and slides are very important. It is very surprising how exceedingly few slides are free from blemishes when examined on a dark ground.

Dark-ground Illumination with a Dry Condenser and Stop.—In all cases I use the ordinary paraffin lamp with ½-inch wick as the source of illumination.

I use Watson's parachromatic condenser in conjunction with a Travis's expanding stop, and for the bull's-eye the field lens of a No. 2 or 3 ordinary ocular, and as objective a Leitz 8 mm. or ⅓ in. apochromatic of N.A. 0·65. After long trials I am convinced that this method is by far the quickest and most convenient for general use in the *search* for these organisms. There is no oil to creep on the surface of the stage when the slide is moved freely about, the field is extensive and uniform, and the thickness of the slide is of no importance so long as it does not exceed 1·6 mm. If a small arc or Nernst electric light were used the illumination would be much more brilliant and the spirochætes seen with greater ease, but I have always used the simple paraffin lamp, and find this quite sufficient provided, of course, the room is not flooded with brilliant sunlight, when it is quite or nearly impossible to see them.

Dark-ground Illumination with an Oil-immersion Condenser and Stop.—Here Watson's holoscopic condenser was used with the same expanding stop. The leptospira, when examined with this illumination, either with the 8 mm. objective and compensating ocular 18, or better, with the $\frac{1}{10}$-in. oil-immersion objective fitted with an iris or funnel stop, were remarkably brilliant, and with the latter objective the spirals most beautifully seen. Disadvantages: the area of illumination is small, and it was much more difficult to find a spirochæte when these were few.

If a bull's-eye is used the field of illumination is large, but it is not nearly as brilliant as without its use.

Dark-ground Illumination with Special Illuminator.—Leitz' dark-ground condenser was used, and with $\frac{1}{10}$-in. objective fitted with Leitz iris behind the back lens of the objective, to cut down its N.A., the results are extraordinarily brilliant, and with the lowest eye-piece there is a large field for hunting, whilst a more powerful ocular brings out the fine structure of the spirochætes exceedingly well.

The thickness of the slides must not exceed 1·1 mm.

Dark-ground illumination with either of the above methods may be used on stained films, either mounted or unmounted. In the latter case the stained film is examined without a cover-glass, a method which the writer introduced many years ago for the detection of *Treponema pallidum*, but of course in this case the tube length of the microscope must be greatly increased, but once found, it need never be altered. Full details of this and other methods are given in the author's "Critical Microscopy."

The Writer's New Method of Examining Living Spirochætes.

This is by far the quickest and easiest method of detecting living leptospira that I have tried, both on the leptospira from water and also from emulsion of the kidney of an infected rat, and by means of it I can examine the same spirochæte in the living and subsequently in the stained condition. It disposes of a cover-glass and the trouble of cleaning that, and the only real difficulty is to clean the slide so thoroughly that a drop of water can be spread over its surface. For this purpose I keep on the table a pot of paste made up of whiting (pulv. creta prep.) and water, and I rub this on the surface of the slide, and then polish with a clean cloth. If successful the water will spread over the surface in a thin and uniform layer. If, as often happens, the water runs up into tenticular globules, it is impossible to examine.

Take two or three clean slides of about the same thickness; on one make a mark with a grease pencil towards the end. Place this slide on the stage of the microscope, which may be inclined at a comfortable angle; with the 8 mm. objective and ocular No. 2 obtain a good, dark background, with, of course, the tube of the microscope pulled out to the correct extent for an uncovered object (which will be about the full length of the draw tube on the Continental-sized microscope). Having got everything in adjustment, remove the slide. On this slide, or on another clean slide, spread out a drop of the material containing leptospira in as thin a film as possible. Examine this, at once, under the dark ground obtained as above by a dry condenser with a stop and bull's-eye, and the spirochætes will appear remarkably clear and sharp, much better than when examined with a cover-glass and shorter tube. It is very interesting to follow the rapid movements of a leptospira, even with the low magnification, and to notice that as soon as the film begins to dry the thread-like, almost perfectly straight structure, not the least like a spirochæte, begins to throw itself into coarse spirals, and immediately the film dries the leptospira changes almost instantaneously in appearance from a delicate silvery-white organism to that of a coarse, thick, yellow structure quite unlike the spirochæte in the living condition. If, as soon as the film is dry, the position of the spirochæte under observation be marked by making a ring round it with a diamond marker, or its exact position logged, it is quite easy to remove the slide, fix and stain the film, and examine the same organism in the stained condition, with the oil immersion objective.

Stained Preparations.—Leptospira, like *T. pallidum* are not easily or readily stained, but probably the best method is to fix the film whilst wet over osmic vapour, or, as I prefer, over iodine,

for a few seconds, and when dry in absolute or methylic alcohol for five to ten minutes, and subsequently staining in Giemsa in the usual way, i.e., one drop of the stain to 1 c.c. of water, overnight.

Silver Staining, when successful, is by far the most distinctive, and brings out the minute spirals of leptospira excellently. After many years of failures, with occasionally a success, with silver staining, I have at last devised a method which never fails to give beautiful results with leptospira in water, and the preparations are quite clean, and, as far as I can tell, permanent. It is simply a modification of Fontana's method.

Place the air-dried or alcohol-fixed thin film in a wide-mouthed bottle containing acid tannic 5, acid carbolic 1, water 100. Allow it to remain three or four hours or more; the longer the time in this mordant the deeper will be the staining, but also the more the background will be stained.

Wash thoroughly under the tap; then rinse well with distilled water. Pour on the wet film a few drops of the following silver solution: To a solution of silver nitrate, 2½ or 5 per cent. in distilled water, add a few drops of liq. ammon. fort., till the sepia precipitate just dissolves when the solution is thoroughly shaken. Now add to this solution, very carefully, a few drops of fresh silver nitrate solution till the resulting liquid is slightly turbid. Allow the silver solution to act for three or four minutes, when the preparation will turn a faint yellowish-brown. Thoroughly wash the slide with distilled water. When examined the leptospira are clearly seen.

To make the preparation a permanent one, to remove any staining of the background, and to blacken the staining of the leptospira, I place the slide in ordinary toning solution that one uses in photography. To about one ounce of water in a developing dish add 4 drops of a 10 per cent. solution of ammonium sulphocyanide and 2 drops of a gold solution (1 gr. to 1 dr). Allow the slide to remain in this till the film is blackened, a matter of a few minutes. Wash well with water, then pour on a 5 per solution of hyposulphite of soda, allow it to act for a minute or so. Finally, well wash and dry.

This method of staining or impregnating with silver has given me most beautiful preparations of leptospira in water, in which the spirochætes can be picked out with quite low powers and which show under high powers the minute spirals very distinctly. The method is absolutely fool-proof, the solutions will all keep indefinitely, and the exact strength of the solutions, or the time of their action, seems of no importance.

I have only tried it once on a film from the kidney of an infected rat, but the result was not so good, as all the other structures stained. I think this difficulty will be overcome, probably by the previous use of Ruge's solutions (acetic acid 1, formalin 2, water 100), and then the silver method will, I think, displace all other methods for diagnostic purposes.

Relief Staining, i.e., the examination in a coloured medium, in which the organisms do not stain, but show up on a coloured background, is quite an old method of examining protozoa, &c., and was used by Certes as far back as 1888. Much more recently Burri used indian ink, Nitsche and Harrison used collargol and Benian used congo red and after-treatment with acid alcohol. I have been working on this subject for some years, and find that indian ink and collargol are too coarse; Benian's preparation does not keep. I have tried many other stains, such as congo red alone, anilin blue, acid fuchsin, cyanin or chinolin blue, opal blue and a host of others. The one which has given me the best results, and apparently permanent preparations, is a strong or saturated solution of nigrosin.

This is used precisely as in the indian ink method: One drop of the nigrosin solution and one drop of the water containing the leptospira are mixed on a slide, and then spread out in a film, allowed to dry, and examined with an oil immersion objective. The only difficulty is that these watery solutions do not spread well unless the slide is perfectly grease-free, and then probably the best parts to examine are towards the margins, where the spirochætes or other protozoa come out a beautiful pearly white on a blue-black, non-granular, background.

As a method of examining the fine structure, such as the minute spirals or flagellum, I think it has no equal, but as a method of spotting or detecting spirochætes it is the very worst method possible, as by its means we begin by diluting the material. When such a film is examined under the highest powers, I find Wratten's screens, Nos. 50 and 15 used together, very greatly improve the optical powers of the objective.

I have entered into the subject of methods of examination somewhat fully, as the leptospira are by no means easy objects, and as dark-ground illumination seems to be regarded with some awe by many microscopists.

In this country I have found the following pathogenic and free-living leptospira:—

Leptospira icterohæmorrhagiæ in the Common Rat in England.

I was the first to describe, in 1918 [5], the occurrence and minute structure of these spirochætes in the kidney of the rat in England. I examined the kidneys of 100 rats killed in this district, and found nine harboured these leptospira. Out of seventeen rats from a private estate near here six were infected, i.e., more than 35 per cent.

The number of spirochætes found in the emulsion of the kidney of the nine positive rats varied considerably. In the first and last rat they were very numerous, as many as eight spirochætes per field were found in the former, and large masses in the latter.

The length of each rat examined was noted, and I stated then that I thought the half-grown

rats of about 7 to 8 in. long were more likely to be infected than the very large or very small rats.

Schüffner and Keunen have since (1923) confirmed my statement. They say: "The low incidence among the young rats in Amsterdam is surprising, considering the high chance of infection to which they are exposed."

With further experience, I should say that 9 per cent. is a very low estimate, and I should expect to find 20 to 30 per cent. of adult rats infected.

Leptospira icterohæmorrhagiæ in Dogs.

On September 10, 1925, Lieut.-Col. H. W. Woodhall, M.F.H., wrote asking my help in trying to elucidate a disease which was causing great havoc among the young foxhounds of the South Dorset Hunt. They had apparently been troubled with the disease for some years, but he says, "during this year the whelps are dying like flies from a disease known as yellows." At my request the heart, liver, kidney and lungs of the next animal that died was sent to me on September 26.

I thought that the disease might possibly be infective jaundice, or even a tick-borne disease, as some years ago I found piroplasma in the blood of a cow in that neighbourhood which was suffering from red water fever. My examination, however, proved entirely negative. On September 30 the same organs from another dead pup were sent, and these were smaller in size and were in a fresher condition.

In fresh cover-glass preparations made from the outer part of the kidney I saw a very few spirochætes in fresh preparations, and subsequently in films stained with Giemsa I found, after a very prolonged hunt, a few definite leptospira, which on critical examination were indistinguishable from the *L. icterohæmorrhagiæ*.

I learnt a little later that Okell, Dalling and Pugh had previously, in 1925 [7], described the occurrence of spirochætes in the leptospiral jaundice of dogs.

Leptospira in Water in England.

In 1923 I found free-living leptospira in tap and other water in this area, and reported my experiences and methods somewhat fully in a popular science journal, *English Mechanics* [6].

"At first I took samples of water from various ponds and pools in the neighbourhood, and centrifuged about 30 c.c. of this at 1,540 revolutions per minute for about three minutes, or a smaller quantity, about 2 c.c., at 7,700 revolutions per minute for the same time, but in no case did I succeed in finding these minute organisms.

"Some time later I noticed by accident that a large bottle—a Winchester quart—which was filled from time to time with water from the main, and kept in the garage for filling up the radiator, had a greenish-brown colour on the sides and a brownish layer at the bottom. The bottle, which had been perfectly clean at first, was filled from time to time from the same tap. The bottle was emptied of all but about six ounces, and this water was thoroughly shaken up and the sides and bottom scraped. This water was poured into a perfectly clean bottle and allowed to stand. Specimens of this taken from about the middle were centrifuged as before, but no spirochætes were found in the deposit. Films made, however, from the sediment in the bottle showed comparatively numerous typical actively-moving leptospira.

"Having once found these organisms, I again examined some of the ponds and ditches which had proved negative previously, taking out a little of the brown and slimy part, and on making films from this I often met with a small number of leptospira. I examined the brown, slimy weed and the water, which was decidedly brackish, from a dock and found a few typical specimens. So far as my experience goes, I am inclined to think that these harmless leptospira might probably be found in almost any stagnant or slow-running water, especially if some of the green, slimy or vegetable matter is used to make films. I have found them, too, in the slimy layers of the bird bath in the garden, but in no case were they as numerous as in the bottle with the clear tap water."

Leptospira—a New Habitat.

In my search during the last two years for other free-living leptospira in nature, I came across quite a new habitat for these organisms. In my garden, which is on very deep sand and gravel and situated in one of the highest and dryest positions in the town, the gardener had dug a hole in the mould, filled it with dead leaves swept up from the garden, covered this with manure, and finally covered the whole with mould. On taking some of this manure, dead leaves and soil, and adding water, I found in the resulting infusion numerous leptospira. From which of the three elements did they come? I examined infusions made with soil, mould and worm casts from various parts of the garden, but found no spirochætes. I similarly examined various manures, both old and new, without success, but whenever I take the damp, dead, decayed leaves well away from the surface, even during the dry weather, and add tap, boiled or distilled water, very thoroughly stir up and allow a few minutes for the heavy part of the dirt to settle, I invariably find active-moving leptospira. At first they are not generally very easy to find, possibly owing to the turbidity of the water, and not a few are quite motionless, merely moving with the stream of fluid, but in twenty-four hours or thirty-six hours they have increased considerably, and are more active in their movements. They are usually associated with other small spirochætes and flagellated protozoa. If there has been rain during the day before the specimen is taken, the leptospira are probably present in their largest numbers in three or four hours after making an infusion. After the third or fourth day the leptospira diminish in number and many are dead, whilst various forms of bacterial life have greatly in-

creased, and at the end of five, six or seven days no more are to be found; evidently the leptospira have been overcome by the enormous number of bacteria.

These observations seem to point very clearly to the fact that the leptospira are present in the damp, dead, decaying leaves as such, and not in a spore or granule stage only.

The disappearance of leptospira from the infusion as soon as bacterial and other putrefactive changes occur, is quite in accordance with Noguchi's [8] experiments on the effects of polluted water, soil and fæces. He says: "The spirochæte of infectious jaundice is a very delicate organism, and is rapidly overwhelmed by most of the bacteria from intestinal contents, sewerage, or soil."

Hindle [9], 1925, on the other hand, actually recommends that "A portion of human fæces about the size of a pea is mixed in a Petri dish with about 20 c.c. of the water to be examined, and the mixture kept in the dark at a temperature of 25° to 30° C.," as a method of cultivating the water leptospira, and he further states that "the ordinary pathogenic strains of *L. icterohæmorrhagiæ* may be grown in a mixture of fæces and water."

I have tried on a few occasions to grow water leptospira on such a medium, but so far I have failed.

I find that all infusions in which leptospira were found had a neutral reaction to litmus. A free sample of the dead leaves was divided into two parts, to one of which ordinary water was added, to the other fresh normal urine of faint acidity; in the former leptospira were immediately found, and reached a maximum in twenty-four hours, in the latter case only one or two leptospira were seen and these were motionless.

I have found leptospira in infusions of dead damp leaves from other gardens near here. I may mention that I place these leaves in a clean beaker, and add water, and then very thoroughly mix, so that there is only about half an inch of water above the leaves. I find the spirochætes are more numerous in the fluid near the top. As Noguchi has pointed out, the search for the leptospira of jaundice should be made within the aerobic zone immediately below the surface of the culture medium.

Are the Leptospira of Water, &c., Harmless?

The leptospira of water are generally considered to be morphologically indistinguishable from that of jaundice. In my experience there are two different types of leptospira met with in water and in decomposing, dead, rotting leaves; the one, by far the more numerous, is slightly thicker, coarser, and the minute spirals are much more easily seen; the other is generally as long, often indeed longer, but is considerably finer, and the spirals much more delicate and not so readily seen. In the majority of cases I think I could distinguish the coarser but not the finer form from the leptospira of jaundice.

The water or free-living leptospira were generally regarded as having no pathogenic action, but Zuelzer [10 and 11], 1922, found that whilst these organisms from water did not give rise to any disease when inoculated directly into animals, one strain, after cultivation for 1¼ years in a serum medium, proved to be pathogenic to guinea-pigs.

Evidence seems to be accumulating to show that living leptospira may have a wide distribution in nature, and that under certain conditions these apparently harmless spirochætes may become pathogenic. The following facts seem very suggestive.

Several outbreaks of infectious jaundice have been recorded on the Continent as a result of bathing in polluted rivers, ponds, or bathing places. Manson-Bahr [12], 1922, describes the first of such cases in England in a man who fell into the Thames off Gravesend and some days later developed jaundice. Wenyon and Brown, after inoculating guinea-pigs, recovered the leptospira of Weil's disease.

Toyama [13], 1921, states that "The prevalence of Weil's disease is closely associated with conditions of the soil, and in Japan all infected districts are paddy fields or localities with swampy ground. It was noted that owing to the number of cases which occurred farmers became reluctant to work the fields," and "he found that in experimental rice fields the leptospira of Weil's disease will not thrive if the reaction of the water exceeds a certain degree of acidity, whereas if the reaction is alkaline or only slightly acid, as it is after use of the fertilizers commonly employed in Japan, the organism will live and remain virulent for about two months." He notes also "that high incidence of infection among human beings is not associated with a corresponding increase in incidence amongst rats."

Gulland and Buchanan [14], 1924, record an outbreak of infectious jaundice among the coal miners of East Lothian in which eighteen cases occurred.

Buchanan [15], 1925, investigated these mines and found in the greyish-brown, translucent, viscid slime on some of the roofs of the mines definite leptospira, although these were somewhat few in number. Two guinea-pigs were inoculated with 2 c.c. of this material with negative results. On a later occasion two more guinea-pigs were inoculated with double this quantity, i.e., 4 c.c. of a fresh sample of the same glutinous substance; both guinea-pigs died, one on the eleventh and the other on the thirteenth day, from definite spirochætal jaundice, and leptospira were found in all the organs. It is interesting to notice that direct inoculation without any cultivation of the slimy material brought about these results.

We may conclude from the above that free-living leptospira may have a wide distribution in the environments of man, and that under certain conditions, of which we have at present little definite knowledge, they may give rise to leptospiral jaundice in man and in some of the domestic animals.

I cannot help thinking that when these minute

spirochætes have become more generally recognized, that not a few cases of Weil's disease will be found which have been overlooked or regarded as a chill or influenza. It is especially to be remembered that even in definite outbreaks, such as occurred among our soldiers in Flanders, jaundice does not by any means always occur.

Stokes, Ryle and Tytler [16], 1917, state that "of 47 cases diagnosed as Weil's disease, clinically or by communication of the disease to animals, 74 per cent. developed jaundice and 26 per cent. have not shown any coloration."

At another place in the same article they state: "We cannot say definitely in how many cases of Weil's disease jaundice occurs as a clinical sign, but we estimate that it does not occur in more than 60 per cent. of cases in the epidemic with which we are dealing."

It is interesting to note that in one out of six dry films of blood taken from one of their cases, Corporal McG., kindly sent me by Adrian Stokes, I found two leptospira after an exhaustive (and a very exhausting) hunt extending over several days. In this case the films were taken on the second day of the illness, and no jaundice occurred at all. Leptospira were also found in guinea-pigs inoculated with blood from this case by Stokes.

Minute Structure of Leptospira.

The following observations are merely of academic interest. It has been rather a debatable point as to whether leptospira and many other spirochætes possess flagella.

I am now quite convinced that nearly all these organisms have one or more flagella, flagellum-like structures, or end organs, often of considerable length. For this work I have used chiefly films made with one of the relief stains, preferably with nigrosin, as mentioned above, but also well-fixed preparations stained with Giemsa. These were examined under critical conditions with the help of an oil immersion condenser and suitable colour screens. My results after months of work may be recorded in a few lines.

T. pallidum usually has a long, wavy, whip-like flagellum at one or both ends. This has no spirals in its course. This spirochæte further contains a number of dots, beads, or granules along its whole length, one or two of which are of larger size than the rest.

The leptospira, notably the water or free-living form, has also a similar flagellum at one or both ends, and in rare cases I think I have found two flagella at each end, after my friend, Mr. E. M. Nelson, had pointed out their occurrence.

It is very easy to see one or two largish granules in *T. pallidum*, *Spirochæta buccalis*, and also in the leptospira, but Mr. Nelson tells me that the leptospira consist of a tube containing a number of very fine granules, of which one or two of larger size are present. He says: "In your film of leptospira from water, I saw, after some hard work and eye-strain, the spirochætes contained dots. These were very minute and evasive, and the image was a difficult one. So your leptospira is similar to other spirochætes, only the granules are much smaller. I made careful measurements of some, and the dots averaged about 120,000 to an inch."

These facts seem to suggest that leptospira and spirochætes contain a number of spores or granules, and that disease is possibly spread by granules. This would explain why *T. pallidum* is often found only in such small numbers in the primary sore, and it is well known that *L. icterohæmorrhagiæ*, and especially *L. icteroides* of yellow fever, can only be found with difficulty in man and inoculated animals.

S. buccalis from mouth or teeth often also show a flagellum at one or both ends, and in a few I have found and logged specimens with two flagella at each end.

Quite recently I have very distinctly seen that many of the *S. buccalis* have not only long terminal flagella, but have also a number of short, delicate cilia-like projections along both sides, so that the whole spirochæte has somewhat the appearance of a miniature centipede. These projections are very short and do not measure more than 0·5 to 0·75 microns in length. Usually there are five or six of these on each side of the spirochæte.

THE BILHARZIA PROBLEM IN SOUTH AFRICA.

By F. G. Cawston, M.D.Cantab.

Only twice in South Africa during the last ten years have I encountered cercariæ resembling those of schistosoma in isidora other than *Isidora africana* (" Physopsis "), even though I have collected examples from heavily infested pools and, on repeated occasions, exposed them to possible infection from miracidiæ. *I. africana* is unknown west of Port Elizabeth; though I have collected an infested example at Klerksdorp, Transvaal, from a tributary of the Vaal river. The Vaal river had been considered free from bilharzia infection, and there would appear to be a relative absence of the intermediate host from the western part of South Africa.

Isidora tropica (Krauss), whose shell is notoriously polymorphous, should never be mistaken for *I. africana* (Krauss), the columella of the latter shell being obvious to all. *I. tropica* is very heavily infested with amphistome cercariæ throughout the Union and it is a very widely distributed shell. It is probable that those shells in Australia which are known as *Bullinus* and have been shown by Dr. Burton Bradley to be cercariæ-carriers include the intermediate host of those amphistomes which are so common in Australian cattle.

Cercariæ-carriers, whose shells resemble those of *Isidora globosa* (Morelet), which I have found infested with cercariæ resembling schistosoma at Lorenço Marques, are found right across Central Africa from Portuguese East Africa to Sierra Leone.

Limnæa natalensis (Krauss) and *Limnæa truncatula* (Müller), the latter not so common as it is in England, are the common carriers of fasciola infestation in South Africa. The intermediate host in Southern Rhodesia is unknown; Professor MacKay has just incriminated *Limnæa brazieri* in New South Wales.

The mere presence of *I. africana* (Krauss) in any locality through which bilharzia carriers are constantly travelling must be regarded as a risk to infection. At as high an altitude as Mulder's Drift in the Transvaal, I examined over 900 examples of this species from a pool on a farm before I found the cercariæ. It was not possible to trace the source of infection, but was probably due to visitors from Zeerust. A reviewer in the *Medical Journal of South Africa* does not consider the mere presence of *I. africana* (Krauss) warrants special measures for its destruction. Of special interest in this connection is the discovery by me of this snail in the Hartebeest-poort Dam, where no prophylactic measures had been enforced to keep down the large number of fresh-water snails that were breeding in the shallow portions of this popular picnic-place for Pretoria and Johannesburg pleasure parties. Previous to this discovery I had myself collected the species heavily infested with schistosoma from one of the rivers that feeds the dam and had treated a boy from this neighbourhood who was heavily infested with the bilharzia parasites. The same writer (C. L. L.)

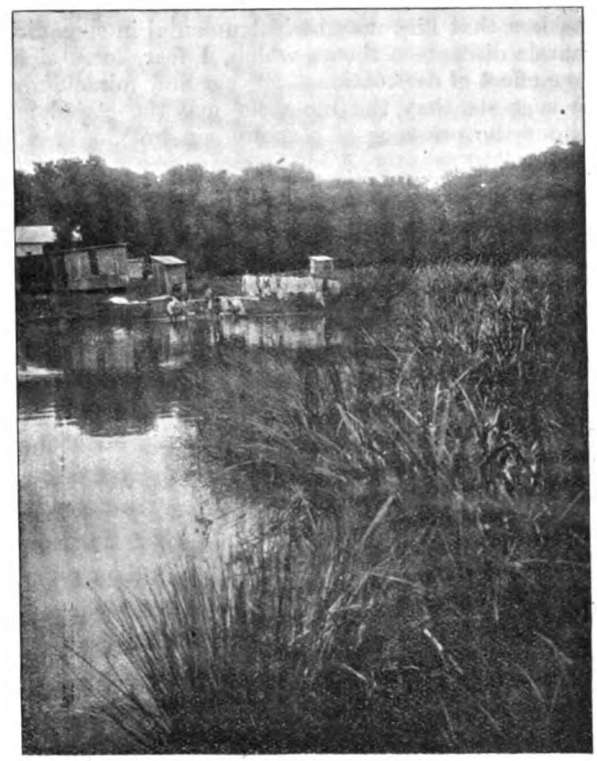

Fig. 1.—The Sydenham Pool, Durban, showing *Cyperus immensus* in profusion.

Fig. 2.—The Sydenham Pool, Durban. Favourite haunt of *Isidora africana*.

considers that flies may be instrumental in spreading bilharzia disease—a theory which, I fear, loses sight of the effect of desiccationon the egg and miracidium, and .suggests that the life-cycle may be completed without the presence of a molluscan host.
